A striking example of “old” biotechnology (in which a microorganism is coaxed into making a valuable product) merging with “new” biotechnology (which uses recombinant DNA) is the emerging field of cyanobacteria-produced plant secondary metabolites. Plants make these small-molecule metabolites to protect themselves against infections, injuries, and environmental factors. Many of the metabolites are strong antioxidants that react with and eliminate harmful oxidants such as oxygen atoms with unpaired electrons (superoxides) in cells under stress. Because human cells in disease states produce such oxidants that harm tissues, there is intense interest in using certain secondary metabolites that plants produce as drugs. Unfortunately, it takes a huge quantity of plants to obtain enough of a given antioxidant for clinical use.

This is where cyanobacteria come in. Cyanobacteria (sometimes incorrectly called blue-green algae) are photosynthetic single-celled organisms that grow well under light conditions in ponds or vats in the

lab. Although they are not plants, cyanobacteria have genes encoding some of the enzymes involved with secondary metabolite production. Using recombinant DNA technology, genes from plants that encode other needed compounds in the pathway of certain antioxidants (specifically, phenylpropanoids) have been inserted into cyanobacteria, turning these organisms into factories that produce plant metabolites for clinical use.

▶ 18.1 DNA from Different Sources Forms Recombinant DNA

- **Recombinant DNA** is formed in the laboratory by combining at least two DNA sequences from different sources. **Review Figure 18.1**

recombinant DNA A DNA molecule made in the laboratory that is derived from two or more genetic sources.

- Many restriction enzymes make staggered cuts in the two strands of DNA, creating fragments that have **sticky ends** with unpaired bases.

sticky ends On a piece of two-stranded DNA, short, complementary, one-stranded regions produced by the action of a restriction endonuclease. Sticky ends facilitate the joining of segments of DNA from different sources.

- DNA fragments cut with restriction enzymes can be used to create recombinant DNA. DNA molecules from different sources can be cut with the same restriction enzyme and spliced together using **DNA ligase**. **Review Focus: Key Figure 18.2**

DNA ligase Enzyme that unites broken DNA strands during replication and recombination.

▶ 18.2 There Are Several Ways to Insert DNA into Cells

- One reason to make recombinant DNA is to **clone** a particular gene or other DNA sequence, either for sequencing and subsequent analysis or to produce a protein product in quantity.

clone

[Gk. *klon*: twig, shoot] (1) Genetically identical cells or organisms produced from a common ancestor by asexual means. (2) To produce many identical copies of a DNA sequence by its introduction into, and subsequent asexual reproduction of, a cell or organism.

- Bacteria, yeasts, and cultured plant and animal cells are commonly used as hosts for recombinant DNA. The insertion of foreign DNA into host cells is called **transformation** or (for animal cells) **transfection**. Transformed or transfected cells are called **transgenic cells**.

transformation (1) A mechanism for transfer of genetic information in bacteria in which pure DNA from a bacterium of one genotype is taken in through the cell surface of a bacterium of a different genotype and incorporated into the chromosome of the recipient cell. (2) Insertion of

recombinant DNA into a host cell.

transfection Insertion of recombinant DNA into animal cells.

- Various methods are used to get recombinant DNA into cells. These include chemical or electrical treatment of the cells, the use of viral vectors, and injection. *Agrobacterium tumefaciens* is often used to insert DNA into plant cells.
- To identify host cells that have taken up a foreign gene, the inserted sequence can be tagged with one or more **reporter genes**, which are genetic markers with easily identifiable phenotypes. **Selectable markers** allow for the selective growth of transgenic cells. **Review Figures 18.3, 18.4**

reporter gene A genetic marker included in recombinant DNA to indicate the presence of the recombinant DNA in a host cell.

selectable marker A gene, such as one encoding resistance to an antibiotic, that can be used to identify (select) cells that contain recombinant DNA from among a large population of untransformed cells.

- Replication of the foreign gene in the host cell requires that it become part of a segment of DNA that contains a **replicon** (origin and terminus of replication).

replicon A region of DNA replicated from a single origin of replication.

- **Vectors** are DNA sequences that can carry new DNA into host cells. Plasmids and viruses are commonly used as vectors.

vector (1) An agent, such as an insect, that carries a pathogen affecting another species. (2) A plasmid or virus that carries an inserted piece of DNA into a bacterium for cloning purposes in recombinant DNA technology.

▶ 18.3 Any Sequence of DNA Can Be Used for Cloning

- DNA fragments from a genome can be inserted into host cells to create a **genomic library**. **Review Figure 18.5A**

genomic library All of the cloned DNA fragments generated by the breakdown of genomic DNA into smaller segments.

- The mRNAs produced in a certain tissue at a certain time can be extracted and used to create **complementary DNA (cDNA)** by **reverse transcription**. **Review Figure 18.5B**

complementary DNA (cDNA) DNA formed by reverse transcriptase acting with an RNA template; essential intermediate in the reproduction of retroviruses; used as a tool in recombinant DNA technology; lacks introns.

cDNA See complementary DNA.

reverse transcription Production of DNA using an RNA template.

- PCR products can be used for cloning. Synthetic DNA containing any desired sequence

can be made in the laboratory.

► 18.4 Several Tools Are Used to Modify DNA and Study Its Function

- **CRISPR** technology can be used to inactivate or mutated any gene. **Review Figure 18.6, Activity 18.1**

CRISPR In archaea, clustered regularly interspaced short palindromic sequences in DNA that are adjacent to sequences from invading viruses. When the two sequences are transcribed, the RNA binds a complementary RNA that binds a nuclease, Cas9, that can cleave and inactivate the genome of the invading virus. This mechanism can be adapted for inactivating and mutating any gene.

- Gene silencing techniques can be used to inactivate the mRNA transcript of a gene, which may provide clues to the gene's function. Artificially created **antisense RNA** or siRNA can be added to a cell to prevent translation of a specific mRNA. **Review Figure 18.7**

antisense RNA A single-stranded RNA molecule complementary to, and thus targeted against, an mRNA of interest to block its translation.

- **DNA microarray** technology permits the screening of thousands of cDNA sequences at the same time. **Review Figure 18.8, Animation 18.2**

DNA microarray A small glass or plastic square onto which thousands of single-stranded DNA sequences are fixed so that hybridization of cell-derived RNA or DNA to the target sequences can be performed.

► 18.5 DNA Can Be Manipulated for Human Benefit

- **Biotechnology** is the use of living cells to produce materials useful to people.

biotechnology The use of living cells or organisms to produce materials useful to humans.

- **Expression vectors** allow a transgene to be expressed in a host cell. **Review Figure 18.9, Activity 18.1**

expression vector A DNA vector, such as a plasmid, that carries a DNA sequence for the expression of an inserted gene into mRNA and protein in a host cell.

- Recombinant DNA techniques have been used to make medically useful proteins. **Review Investigating Life: Producing TPA**
- **Pharming** is the use of transgenic plants or animals to produce pharmaceuticals. **Review Figure 18.10**

pharming The use of genetically modified animals to produce medically useful products in their milk.

- Because recombinant DNA technology has several advantages over traditional agricultural biotechnology, it is being extensively applied to agriculture.
- Biotechnology may allow us to adapt the plant to the environment, rather than vice versa.
- Synthetic biology involves creating new cells with artificial DNA made in the laboratory.
- There is public concern about the application of recombinant DNA technology to food production.

Review

8.4 CRISPR technology can be used to alter and inactivate specific genes.

8.5 The use of biotechnology has ethical and environmental ramifications.

Original Paper: Gantz, V. M. and E. Bier. 2015. The mutagenic chain reaction: A method for converting heterozygous to homozygous mutations. *Science* 348: 442-444.

Mosquitoes in the genus *Anopheles* transmit the parasite *Plasmodium* to humans, resulting in more than half a million deaths from malaria every year. Some genetic strains of *Anopheles* carry a recessive gene that, when homozygous, makes them inhospitable to the parasite.

Gene knockout methods have been used to produce large numbers of mosquitoes carrying the resistance mutation, but since only one of the two alleles is mutated by this method, release of these insects into the wild will not result in a rapid spread of malaria resistance. A method to mutate both alleles, producing mosquitoes homozygous for resistance, would result in a more rapid spread of resistance.

Gantz and colleagues developed a method called the mutagenic chain reaction (MCR) to address this. They used CRISPR technology to convert heterozygous mutations to homozygous ones in the model organism *Drosophila melanogaster*. The CAS9 enzyme was used to cut the body-color gene carried on the X chromosome. This produced the first mutation: to yellow body ([Figure A](#)). This mutated gene was replicated by the fly's own DNA repair system resulting in a homozygous yellow fly ([Figure B](#)).

Figure A

Figure B

Figure C shows how MCR inheritance works. CRISPR technology created a male fly with the mutated yellow gene (marked in yellow on [Figure B](#)) on the X chromosome. When this fly was crossed with a homozygous wild-type female, the female offspring inherited one X chromosome with the yellow allele from the male parent, and one X chromosome from the female parent that had the wild-type allele that was immediately converted to a mutated (yellow) allele. So these females were yellow.

Figure C

Questions

1. How do the genotypes in the CRISPR cross compare with those produced by sex-linked Mendelian inheritance?
2. Why do none of the male offspring have the mutated allele?
3. Explain why this method would result in a rapid increase in the frequency of the mutated alleles in the population if the flies were released to the wild.
4. The researchers plan to use similar technology to fight malaria. What else would be needed to enable this

technology to combat malaria?

5. What are some possible risks of this technology? How can these risks be minimized?

Stem Cell Therapy

Ruby was getting old, and like many in her age group, she developed arthritis in her hips. “Arthritis” means joint inflammation. A breakdown of cartilage between the bones was causing inflammation and pain. Her loved ones could hear the bones in her hips grinding against one another as she tried to walk. The doctor recommended a hip replacement, whereby an artificial joint is inserted. But Karen and Dave did something different for their beloved collie.

A veterinary surgeon removed fat cells from Ruby’s body and isolated mesenchymal stem cells from these tissues. Stem cells are actively dividing, unspecialized cells that have the potential to produce different cell types depending on the signals they receive from the body. Mesenchymal stem cells are able to differentiate into various kinds of connective tissue, including bone, cartilage, blood vessels, tendons, and muscle. Ruby’s stem cells were injected into her hip, and months later she was much better. She was back to her old frisky self, enjoying walks and car rides and even walking up stairs without assistance. Her owners were ecstatic.

Stem cell therapy in humans has been much in the news of late. The basic idea is to inject stem cells into damaged tissues, where they will differentiate and form new, healthy tissues. Many procedures are being tried experimentally, and widespread clinical use is on the horizon. Stem cell treatments have, however, been given to animals for more than a decade. Dogs like Ruby have been returned to their owners with a new lease on life, horses have been returned to racing or to the show ring, and even zoo animals have been treated successfully.

The processes by which an unspecialized stem cell proliferates and forms specialized cells and tissues with distinctive appearances and functions are similar to the developmental processes that occur in the embryo. Much of our knowledge of developmental biology has come from studies on model organisms such as fruit flies, nematodes, frogs, sea urchins, mice, and the small flowering plant *Arabidopsis thaliana*. Eukaryotes share many similar genes, and the cellular and molecular principles underlying their development also turn out to be similar. Thus discoveries from one organism aid us in understanding other organisms, including ourselves.

What are the potential uses of stem cells?

19.1 The Four Major Processes of Development Are Determination, Differentiation, Morphogenesis, and Growth

Development is the process by which a multicellular organism, beginning with a single cell, goes through a series of changes, taking on the successive forms that characterize its life cycle (**Figure 19.1**). After the egg is fertilized it is called a zygote, and in the earliest stages of development a plant or animal is called an **embryo**. Sometimes the embryo is contained within a protective structure such as a seed coat, an eggshell, or a uterus. Embryogenesis results in a new organism with a body plan characteristic of its species. Many organisms continue to develop throughout their life cycles, with development ceasing only at death.

development The process by which a multicellular organism, beginning with a single cell, goes through a series of changes, taking on the successive forms that characterize its life cycle.

embryo [Gk. *en*: within + *bryein*: to grow] A young animal, or young plant sporophyte, while it is still contained within a protective structure such as an egg, uterus, or seed.

Figure 19.1 From Fertilized Egg to Adult The stages of development from zygote to maturity are shown for an animal and for a plant. The blastula is a hollow sphere of cells; the gastrula has three cell layers.

focus your learning

In the embryo, determination of the fate of a cell occurs before actual cell differentiation.

Experimental manipulations indicate that a differentiated cell in a plant or animal has the whole genome of the organism and the potential to form all other cells of that organism.

Cloning of plants and animals using differentiated cells or cell nuclei has several potential uses.

Pluripotent stem cells can be obtained from animal embryos or formed from differentiated cells in the laboratory.

Development involves four distinct but overlapping processes

As an organism progresses from a fertilized egg to a mature adult, four processes occur:

- **Determination** sets the developmental *fate* of a cell—what type of cell it will become—even before any characteristics of that cell type are observable. For example, the mesenchymal stem cells described in the story opening this chapter look unspecialized, but their fate to become connective tissue cells has already been determined.
- **Differentiation** is the process by which different types of cells arise, leading to cells with specific structures and functions. For example, mesenchymal stem cells differentiate to become muscle, fat, tendon, or other connective tissue cells.
- **Morphogenesis** (Greek for “origin of form”) is the organization and spatial distribution of differentiated cells into the multicellular body and its organs.
- **Growth** is the increase in size of the body and its organs by cell division and cell enlargement.

determination In development, the process whereby the fate of an embryonic cell or group of cells (e.g., to become epidermal cells or neurons) is set (becomes **determined**).

differentiation The process whereby originally similar cells follow different developmental pathways; the actual expression of determination.

morphogenesis (more' fo jen' e sis) [Gk. *morphe*: form + *genesis*: origin] The development of form; the overall consequence of determination, differentiation, and growth.

growth An increase in the size of the body and its organs by cell division and cell expansion.

Determination and differentiation occur largely because of regulation of gene expression, a topic explored in [Chapter 16](#). You'll see many of the mechanisms described in that chapter here. The cells that arise from repeated mitoses in the early embryo may look the same superficially, but they soon begin to differ in terms of which of the thousands of genes in the genome are expressed.

Morphogenesis involves not just differential gene expression but also intercellular signaling (see [Chapter 7](#)). Morphogenesis proceeds in several ways, influenced by:

Cell division—a key event in both plants and animals

Cell expansion—especially important in plant development, in which a cell's position and shape are constrained by the cell wall

Cell movements—very important in animal morphogenesis

Apoptosis (programmed cell death)—essential in organ development

Growth occurs by cell enlargement. In some cases, cell enlargement is coupled to cell division, so the average cell size remains the same as the tissue grows; in other cases (especially in plant tissues), cells enlarge without dividing, so the average cell size increases. Growth continues throughout the individual's life in some organisms, but reaches a more or less stable end point in others.

As development proceeds, cell fates become restricted

During development, an undifferentiated cell will become part of a particular type of tissue—this is referred to as **cell fate**. Cell fate determination occurs as the embryo develops. The timing of this determination varies with the organism, but it is typically quite early. One way the timing can be revealed is to transplant cells from one embryo to a different region of a recipient embryo (**Figure 19.2**). Do the transplanted cells adopt the differentiation pattern of their new surroundings, or do they continue on their own path, with their fate already sealed?

cell fate The type of cell that an undifferentiated cell in an embryo will become in the adult.

Figure 19.2 A Cell's Fate Is Determined in the Embryo Transplantation experiments using amphibian embryos show that the fate of cells is determined as the early embryo develops.

 Activity 19.2 **Cell Fates Simulation** www.Life11e.com/ac19.2

Experiments on amphibian embryos indicate that determination happens early in development. If the donor tissue is from an early-stage embryo (blastula), it adopts the fate of the new surroundings. In this case, cell fate has not been determined and is influenced by the

extracellular environment. But if the donor tissue is from an older embryo (gastrula), it continues on its original developmental path. In this case, cell fate has already been determined and is no longer influenced by the extracellular environment.

Cell fate determination is influenced by changes in gene expression as well as the extracellular environment. You can't see cell fate determination by looking at an embryo under the microscope—cells do not change their appearance when they become determined. Rather, the changes that mark determination are within the cell's molecular makeup. Determination is followed by differentiation—the actual changes in structure and function that result in different cell types. *Determination is a commitment; the final realization of that commitment is differentiation.*

During animal development, cell fate becomes progressively more restricted. This can be thought of in terms of **cell potency**, which is a cell's potential to differentiate into other cell types:

cell potency In multicellular organisms, an undifferentiated cell's potential to become a cell of a specific type. (See multipotent, pluripotent, totipotent.)

The cells of an early embryo are **totipotent** (*toti*, “all,” + *potent*, “capable”); they have the potential to differentiate into any cell type, including more embryonic cells.

In later stages of the embryo, many cells are **pluripotent** (*pluri*, “many”); they have the potential to develop into most other cell types, but they cannot form new embryos.

Through later developmental stages, including adulthood, certain stem cells are **multipotent**; they can differentiate into several different, related cell types. Mesenchymal stem cells (see the opening story of this chapter) are one kind of multipotent stem cell.

Many cells in the mature organism are **unipotent**; they can produce only one cell type—their own.

totipotent [L. *toto*: whole, entire + *potens*: powerful] Possessing all the genetic information and other capacities necessary to form an entire individual. (Contrast with multipotent, pluripotent, unipotent.)

pluripotent [L. *pluri*: many + *potens*: powerful] Having the ability to form all of the cells in the body. (Contrast with multipotent, totipotent, unipotent.)

multipotent Having the ability to differentiate into a limited number of cell types. (Contrast with pluripotent, totipotent, unipotent.)

unipotent An undifferentiated cell that is capable of becoming only one type of mature cell. (Contrast with totipotent, multipotent, pluripotent.)

Cell differentiation is sometimes reversible

Once a cell's fate is determined, the cell differentiates. However, under the right experimental conditions, a determined or differentiated cell can become undetermined again. In some cases the cell can become totipotent, able to form an entire organism with all of its differentiated cells.

PLANT CELL TOTIPOTENCY

A carrot root cell normally faces a dark future. It cannot photosynthesize and generally does not give rise to new carrot plants. However, in 1958 Frederick Steward at Cornell University showed that if he isolated cells from a carrot root and maintained them in a suitable nutrient medium, he could induce them to dedifferentiate—to lose their differentiated characteristics. The cells could

divide and give rise to masses of undifferentiated cells called calli (singular “callus”), which could be maintained in culture indefinitely. Furthermore, if they were provided with the right chemical cues, the cells could develop into embryos and eventually into complete new plants ([Figure 19.3](#)). Since the new plants were genetically identical to the cells from which they came, they were clones of the original carrot plant.

Figure 19.3 Cloning a Plant

Original Paper: Steward, F. C., M. O. Mapes and K. Mears. 1958. Growth and organized development of cultured cells. II. Organization in cultures grown from freely suspended cells. *American Journal of Botany* 45: 705–708.

When cells were removed from a plant and put into a medium with nutrients and hormones, they lost many of their specialized features—in other words, they dedifferentiated. Did these cells retain the ability to differentiate again? Frederick Steward found that a cultured carrot cell did indeed retain the ability to develop into an embryo and a new plant.

HYPOTHESIS ▶ Differentiated carrot cells can be induced to generate all types of the plant's cells.

METHOD

RESULTS

CONCLUSION ▶ Are differentiated carrot cells unipotent, multipotent, pluripotent, or totipotent?

Cloning an entire carrot plant from a ***differentiated root cell** showed that the root cell contained a complete carrot genome, and that under the right conditions, the cell and its descendants could express the appropriate genes in the right sequence to form a new plant. Many types of cells from other plant species show similar behavior in the laboratory, and in some cases in nature (asexual reproduction). Being able to generate a whole plant from a single cell in the lab is invaluable in agriculture and forestry. For example, trees from planted forests are used in making paper, lumber, and other products. To replace the trees reliably, forestry companies regenerate new trees from the leaves of selected trees with desirable traits. The characteristics of these clones are more uniform and predictable than those of trees grown from seeds.

NUCLEAR TOTIPOTENCY IN ANIMALS

Animal somatic cells cannot be manipulated as easily as plant cells can. However, as you saw with the transplantation experiments on sea urchins, the cells of very early animal embryos are totipotent. In humans this totipotency permits genetic screening (see [Key Concept 15.4](#)) of an embryo. One or two cells can be removed from the embryo and examined to determine whether a certain genetic condition is present. Because of their totipotency, the remaining cells can develop into a complete embryo, which can be implanted into the mother's uterus, where it develops into a normal fetus and infant. A later animal embryo cell won't develop into a complete organism, but the *nucleus* of such a cell has the genetic potential to do so.

Nuclear transfer experiments demonstrate that the genetic information from a single animal cell can be used to create cloned animals. Robert Briggs and Thomas King performed the first such experiments in the 1950s using frog embryos. First they removed the nuclei from unfertilized eggs, forming enucleated eggs. Then, with very fine glass needles, they punctured cells from early embryos and drew up parts of their contents, including the nuclei. Each nucleus was injected into an enucleated egg. They stimulated the eggs to divide, and many went on to form embryos, and eventually frogs, which were clones from the original implanted nuclei. These experiments led to two important conclusions:

- . No information is lost from the nuclei of cells as they pass through the early stages of embryonic development. This fundamental principle of developmental biology is known as **genomic equivalence**.
- . The cytoplasmic environment around a cell nucleus can modify its fate.

genomic equivalence All somatic cells in a complex organism have the entire genome of that organism.

More recent studies have demonstrated that a cell from a fully developed animal can be induced to dedifferentiate and give rise to an entire new individual. In 1996 Ian Wilmut and his colleagues at the Roslin Institute in Edinburgh cloned the first mammal by somatic cell nuclear transfer. This method involves the fusion of a somatic (nonreproductive) cell from an adult animal, containing the donor nucleus, with an enucleated egg. The fully differentiated donor cells were isolated from a Finn Dorset ewe's udder and starved of nutrients for a week, halting the cells in the G1 phase of the cell cycle. One of these cells was fused with an enucleated egg from a Scottish Blackface ewe, and this fused cell began to divide. After several cell divisions, the resulting early embryo was transplanted into the womb of a surrogate mother. Eventually a lamb named Dolly was born ([Figure 19.4](#)). Dolly showed all the characteristics of a Finn Dorset sheep: she carried the same genetic material as the nuclear donor, and thus was a clone of that donor.

1 Cells are removed from the udder of a Finn Dorset ewe.

2 An egg is removed from a Scottish Blackface ewe.

3 Udder cells are deprived of nutrients in culture to halt the cell cycle prior to DNA replication.

6 ...and induced to divide.

7 An early embryo develops and is transplanted into a receptive ewe.

Scottish Blackface sheep (#3)

8 The embryo develops and a Finn Dorset sheep, genetically identical to #1, is born.

Figure 19.4 Cloning a Mammal The experimental procedure described here produced the first cloned mammal, a Finn Dorset sheep named Dolly (shown on the left in the photo). As an adult, Dolly mated and subsequently gave birth to a normal offspring, thus proving the genetic viability of cloned mammals.

A **work with the data** exercise that accompanies this figure may be assigned in **LaunchPad**.

The production of Dolly demonstrated that a fully differentiated cell from a mature organism can revert to a totipotent state, and that this cell can be used to create a new animal. More than 20 animal species, including cats, deer, dogs, horses, pigs, rabbits, and mice, have since been cloned by nuclear transfer. There are several reasons to clone animals:

Expansion of the numbers of valuable animals: One goal of Wilmut's experiments was to develop a method for cloning transgenic animals with useful phenotypes. For example, a cow was genetically engineered to make human growth hormone in her milk. This animal was then cloned to produce additional cows that do the same thing. Only 15 such cows are needed to supply the world's demand for this medication, which is used to treat short stature caused by growth hormone deficiency.

Preservation of endangered species: The mouflon, a small sheep native to the European islands of Sardinia and Corsica, was the first endangered animal to be successfully cloned. Cloning may be the only way to save some endangered species with low rates of natural reproduction, such as the giant panda.

Perpetuation of pets: Many people get great personal benefit from pets, and the death of a pet can be devastating. Companies have been set up to clone cats and dogs from cells provided by their owners. Owners have paid more \$100,000 each to have their pets cloned. Of course, the behavioral characteristics of the beloved pet, which are certainly derived in part from the environment, may not be the same in the cloned pet as in its genetic parent.

Multipotent stem cells differentiate in response to environmental signals

As you learned in the opening story, [stem cells](#) are rapidly dividing, undifferentiated cells that can differentiate into diverse cell types. In plants, stem cells occur in the meristems (see [Key Concept 33.1](#)). In mammals, stem cells are found in adult tissues that need frequent cell replacement, such as the skin, the inner lining of the intestine, and the bone marrow, where blood cells and other types of cells are formed.

stem cell In animals, an undifferentiated cell that is capable of continuous proliferation. A stem cell generates more stem cells and a large clone of differentiated progeny cells. (See *also* embryonic stem cell.)

The stem cells found in adult animals are not totipotent, because their ability to differentiate is limited to a relatively few cell types. In other words, they are multipotent. For example, there are two types of multipotent stem cells in the bone marrow. Hematopoietic stem cells produce red and white blood cells, whereas mesenchymal stem cells (like those used to treat the dog Ruby in the opening story) produce bone and connective tissues, including muscle.

experiment

Original Paper: Black, L. L., J. Gaynor, D. Gahring and C. Adams. 2007. Effect of adipose-derived mesenchymal stem and regenerative cells on lameness in dogs with chronic osteoarthritis of the coxofemoral joints: A randomized, double-blinded multicenter controlled trial. *Veterinary Therapeutics* 8: 272–284.

Arthritis causes significant disability in dogs, especially older ones. In the United States, more than 10 million dogs suffer from arthritis at some point in their lives. A major reason for arthritis at joints is a breakdown of cartilage tissue that acts as a lubricant between the bones. Without it, there is pain and lameness. While working at a biopharmaceutical company serving veterinarians, Linda Black coordinated a study to determine whether multipotent stem cells contained within fat tissue could, in the right environment, make cartilage that would relieve pain and mobility problems in arthritic dogs.

HYPOTHESIS ▶ Stem cells derived from fat can clinically benefit dogs with arthritis.

METHOD

RESULTS

CONCLUSION ▶ Stem cell treatment improves hip function in dogs with arthritis.

work with the data

The experiment was conducted as a randomized, double-blinded, controlled clinical trial (RCT). “Randomized” means that the dogs all had similar clinical presentation and then were assigned to treated or untreated groups at random, with no selection. “Double-blinded” means that neither the scientists giving the injections nor the scientists evaluating the dogs before and after treatment knew which group the dogs were in. “Controlled” means that the dogs treated with stem cells or not were otherwise treated the same (e.g., food, living conditions). **Table A** shows the results of the experiment. Data are presented as mean score ($\pm$ SEM).

Table A

Condition	Treatment	Initial	60 days later
Lameness	Stem cell	2.89 (0.20)	1.78 (0.32)
	Control	2.22 (0.15)	1.89 (0.31)
Pain	Stem cell	2.22 (0.15)	1.56 (0.18)
	Control	2.00 (0.17)	1.89 (0.20)
Motion	Stem cell	2.89 (0.20)	1.89 (0.26)
	Control	2.33 (0.17)	2.11 (0.20)

QUESTIONS

- Why is the RCT considered the “gold standard” for clinical research?
- How did researchers reach the conclusion that the stem cell treatment given to the dogs in the experimental group was effective? What statistical test would you use to evaluate the significance of any differences between the initial and the final observations in Table A (see Appendix B)?
- To determine the time course of any changes in clinical status, dogs were examined at various time periods after injection. The scores for range of motion are reported in **Table B**. Plot these data as percent change in clinical score versus time. What can you conclude about the time course of the effect of stem cells?

Table B

Time (days)	Stem cell group	Control group
Initial	2.89	2.33
30	1.73	2.05
60	1.89	2.11
90	1.85	2.30

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Multipotent stem cells proliferate and differentiate “on demand” in response to environmental signals. For example, hematopoietic stem cells proliferate in the bone marrow in response to growth factors, and the extra stem cells are released into the blood. An important therapy called

hematopoietic stem cell transplantation helps replace cells damaged in some kinds of cancer treatment.

Stem cells can be harvested from the bone marrow or blood of the patient (prior to cancer treatment) or of a donor, and then the cells are injected back into the patient after cancer treatment.

Signals from adjacent cells can stimulate stem cell differentiation. Many controlled experiments have shown that damaged animal tissues (for example, hearts and tendons) that are injected with stem cells can heal more effectively than tissues that don't receive this treatment. As mentioned in the opening story of this chapter, therapy for degeneration of joints due to age or injury is now a well-established practice in veterinary medicine (**Investigating Life: Stem Cell Therapy**).

How stem cells work after injection is not clear. They may actually insert themselves into the damaged tissue and differentiate into new cells of that tissue. Alternatively, injected cells may secrete growth factors and other molecules that induce the cells in the surrounding tissue to regenerate into healthy tissue. Whatever the mechanisms by which multipotent stem cells contribute to the healing of damaged tissues, their use in treating diseases is very promising.

Pluripotent stem cells can be obtained in two ways

As stated earlier, totipotent stem cells that can differentiate into any cell type are found only in very early embryos. In both mice and humans, a slightly later embryonic stage is a hollow sphere of cells called a **blastocyst** (see [Figure 43.4](#)). A group of cells within the blastocyst is pluripotent: they can differentiate into most cell types but cannot give rise to a complete organism. In mice, these **embryonic stem cells (ESCs)** can be removed from the blastocyst and grown in laboratory culture almost indefinitely, given the right conditions. When cultured mouse ESCs are injected back into another mouse blastocyst, the stem cells mix with the resident cells and differentiate to form all the cell types in the mouse, which indicates that ESCs retain their developmental potential while growing in the laboratory.

blastocyst (blass' toe cist) An early embryo formed by the first divisions of the fertilized egg (zygote). In mammals, a hollow ball of cells.

embryonic stem cell (ESC) A pluripotent cell in the blastocyst.

ESC See embryonic stem cell.

ESCs growing in the laboratory can also be induced to differentiate in a particular way if the right signal is provided ([Figure 19.5A](#)). For example, treatment of mouse ESCs with a derivative of vitamin A causes them to form neurons, whereas other growth factors induce them to form blood cells. Such experiments demonstrate both the cells' developmental potential and the roles of environmental signals. This finding raises the possibility of using ESC cultures as sources of differentiated cells to repair specific tissues, such as a damaged pancreas in diabetes, or a brain that malfunctions in Parkinson's disease.

(A) Embryonic stem cells

(B) Induced pluripotent stem cells

Figure 19.5 Two Ways to Obtain Pluripotent Stem Cells Pluripotent stem cells can be obtained either from human embryos (A) or by adding highly expressed stem cell genes to skin cells to transform them into stem cells (B).

Animation 19.1 Embryonic Stem Cells www.Life11e.com/a19.1

ESCs can be harvested from human embryos conceived by in vitro (“under glass”—in the laboratory) fertilization, with the consent of the parents that conceived them. Since more than one embryo is usually conceived in this procedure, there is great interest in clinical studies of ESCs from embryos not used for reproduction. While there is substantial promise in the possibility of using ESCs from human embryos as sources of tissues for transplantation into patients with tissue damage, serious concerns must first be addressed, including the ethical

issue of whether human embryos should be destroyed for this (or any) purpose, and the possibility that stem cells, and tissues derived from them, might provoke an immune response in a recipient (see [Chapter 41](#)).

Shinya Yamanaka and coworkers at Kyoto University in Japan have developed a way to produce pluripotent stem cells that gets around these two problems ([Figure 19.5B](#)). Instead of extracting ESCs from blastocysts, they make pluripotent stem cells from skin cells. They developed this method systematically:

- First they used microarrays (see [Figure 18.8](#)) to compare the genes expressed in ESCs with non-stem cells. They found several genes that were uniquely expressed at high levels in ESCs. These genes were believed to be essential to the undifferentiated state and function of stem cells.
- Next they isolated the genes, coupled them to highly expressing promoters, and inserted them into skin cells (see [Key Concept 18.5](#)). They found that the skin cells now expressed the newly added genes at high levels.
- Finally, they showed that the altered skin cells were pluripotent and could be induced to differentiate into many tissues. They called these cells [induced pluripotent stem cells](#) (**iPS cells**).

induced pluripotent stem cells (iPS cells) Multipotent or pluripotent animal stem cells produced from differentiated cells in vitro by the addition of several genes that are expressed.

Because the iPS cells can be made from skin cells of the individual who is to be treated, an immune response may be avoided. Such cells have already been used for cell therapy in animals for diseases similar to human Parkinson's disease (a brain disorder), diabetes, and sickle-cell anemia. If it can be shown conclusively that iPS cells have the same properties as ESCs, human uses are sure to follow. At this writing, there are numerous clinical trials under way using iPS cells. For example, in Japan they are being used to regenerate cells of the retina in the eye in efforts to reverse macular degeneration.

19.1 recap

Development takes place via the processes of determination, differentiation, morphogenesis, and growth. Cells in the very early embryo have not yet had their fates determined; as development proceeds, their potential fates become more and more restricted. Differentiated cells retain their ability to differentiate into other cell types, given appropriate chemical signals—a fact that has made cloning and stem cell technologies possible.

learning outcomes

You should be able to:

- Interpret expected results from cell transplantation experiments in amphibian embryos with respect to what they tell us about cell fate determination.
- Outline experiments to compare gene expression before and after the reprogramming of gene expression that occurs during cloning.
- Describe the potential uses of reproductive cloning in humans and other animals.
- Compare human embryonic and adult stem cells.

1. What information did transplantation experiments provide about when cell fates are determined and the extent to which the environment can affect determination in early and late embryos?
2. How are stem cells in adult body tissues different from early embryonic stem cells?
3. Cloning involves considerable reprogramming of gene expression in a differentiated cell nucleus so that it acts as it does in a totipotent cell. How would you investigate this reprogramming?
4. There are two considerations for human cloning. In therapeutic cloning, cells from an individual—either genetically altered or not—would be grown into organs for transplantation. In reproductive cloning, nuclear transfer would be used to clone a person. Cloning to produce a new organism has been successfully achieved in animals but not in humans. What are some of the uses for cloning in animals and some potential uses for cloning in humans?

You have learned about the basic processes that occur during development, and seen that cell fate determination occurs before cells differentiate and become specialized. We will now turn to the mechanisms of cell fate determination.

19.2 Gene Expression Differences Determine Cell Fate and Cell Differentiation

The fertilized egg undergoes many cell divisions to produce the many differentiated cells in the body (such as liver, muscle, and nerve cells). How can one cell produce so many different cell types? Determination occurs in two ways:

- **Cytoplasmic segregation** (unequal cytokinesis). Factors that play important roles in setting up the signaling cascades that orchestrate the major events of development may be unequally distributed in the cytoplasm of the egg, zygote, or precursor cell. After cell division, one or more of these factors, generally called **cytoplasmic determinants**, end up in some daughter cells or regions of cells, but not others.
- **Induction** (cell-to-cell communication). A factor is actively produced and secreted by certain cells to induce other cells to become determined.

cytoplasmic segregation The asymmetrical distribution of cytoplasmic determinants in a developing animal embryo.

cytoplasmic determinants In animal development, gene products whose spatial distribution may determine such things as embryonic axes.

induction In embryonic development, the process by which a factor produced and secreted by certain cells determines the fates of other cells.

focus your learning

Polarity may take place early in development, even within the fertilized egg.

Induction, whereby one part of the embryo signals another part to develop in a specific way, is exemplified by the development of the vulva in a nematode.

Cell differentiation during development involves changes in gene expression, as shown by the activation of the transcription factor MyoD in muscle differentiation.

Cytoplasmic segregation can determine cell fate

Some differences in gene expression patterns and determination of a cell's fate happen as a result of cytoplasmic differences among cells. One such cytoplasmic difference is the emergence of distinct “top” and “bottom” ends of an organism or structure; a difference that establishes **polarity**. Many examples of polarity are observed as development proceeds. An axis of polarity is established by our heads and “tails,” as well as between the distal (far) ends of our arms and legs (wrists, ankles, fingers, toes) and their proximal (near) ends (shoulders and hips).

polarity (1) In chemistry, the property of unequal electron sharing in a covalent bond that defines a polar molecule. (2) In development, the difference between one end of an organism or structure and the other.

Polarity may develop early; even within the fertilized egg, the yolk and other factors are often distributed asymmetrically. During ***early development in animals**, polarity is specified by what is called the **animal pole** at the top of the zygote and the **vegetal pole** at the bottom. This polarity can lead to determination of cell fates at a very early stage of development. For example, sea urchin embryos can be bisected at the eight-cell stage in two ways:

animal pole The point at the end of the developing egg where yolk is least concentrated.
vegetal pole The point at the end of the developing egg where yolk is most concentrated.

If the two halves of these embryos (each with four cells) are allowed to develop, the results are dramatically different for the two different cuts:

- . If the embryo is cut into a top half and a bottom half (left, above), the bottom half develops into a small sea urchin and the top half does not develop at all but instead gives rise to a hollow ball of undifferentiated cells.
- . If the embryo is cut into two side halves (right, above), both halves develop into small sea urchins.

These results indicate that the top and bottom halves of an eight-celled sea urchin embryo have *already developed distinct fates*. Such observations led to the model of cytoplasmic segregation shown in **Figure 19.6**. The model states that the cytoplasmic determinants are distributed unequally in the egg cytoplasm. Cytoplasmic determinants include specific proteins, small regulatory RNAs, and mRNAs, and they play roles in directing the embryonic development of many organisms. What accounts for the unequal distribution of these determinants?

Figure 19.6 The Principle of Cytoplasmic Segregation The unequal distribution of some component in the cytoplasm of a cell may determine the fates of its descendants.

Animation 19.2 **Early Asymmetry in the Embryo** www.Life11e.com/a19.2

Inducers passing from one cell to another can determine cell fate

The term “induction” has different meanings in different contexts. In biology it can be used broadly to refer to the initiation of, or cause of, a change or process. But in the context of cellular differentiation, it refers to the signaling events by which cells in a developing organism communicate and influence one another’s developmental fate. Induction involves chemical signals and signal transduction mechanisms. An example of embryonic induction occurs during the development of a reproductive structure of the nematode *Caenorhabditis elegans*.

Caenorhabditis elegans develops from fertilized egg to larva in only about 12 hours, and the worm reaches the adult stage in just 3.5 days. The process is easily observed using a low-magnification dissecting microscope because the body covering is transparent ([Figure 19.7A](#)). Most adult nematodes are hermaphroditic, containing both male and female reproductive organs. They lay eggs through a pore called the vulva on the ventral (lower) surface. During development, a single cell in the overlying gonad, called the anchor cell, induces the vulva to form from six cells on a worm’s ventral surface ([Figure 19.7B](#)). In this case there are two molecular signals: the primary (1°) inducer and the secondary (2°) inducer. Each of the six ventral cells has three possible fates: it may become a primary vulval precursor cell, a secondary vulval precursor cell, or simply become part of the worm’s skin—an epidermal cell. You can follow the sequence of events in [Figure 19.7B](#). The concentration gradient of the primary inducer, LIN-3, is key. (LIN stands for abnormal cell *lineage*.) The anchor cell produces the LIN-3 protein, which diffuses out of the cell and forms a concentration gradient with respect to adjacent cells. Three cells receive more LIN-3 than the others and become vulval precursor cells; cells farther from the anchor cell receive less LIN-3 and become epidermal cells. The cell closest to the anchor cell receives the most LIN-3—enough LIN-3 to trigger a signal transduction response in the closest neighboring cell that results in the expression of the secondary inducer. The secondary inducer then acts on the two adjacent cells. This second induction event results

in the two classes of vulval precursor cells: primary and secondary.

(A) Basic anatomy of *C. elegans*

(B) The influence of LIN-3 on the primary and secondary inducers involved in cell differentiation in *C. elegans*

Figure 19.7 Induction during Vulval Development in *Caenorhabditis elegans* (A)

In the nematode *C. elegans* (shown in false color here), it is possible to follow all of the cell divisions from the fertilized egg to the 959 somatic cells found in the adult. (B) During vulval development, a molecule secreted by the anchor cell (the LIN-3 protein) acts as the primary (1°) inducer. The primary precursor cell (the one that receives the highest concentration of LIN-3) then secretes a secondary (2°) inducer that acts on its neighbors. The gene expression patterns triggered by these molecular switches determine cell fates.

Induction involves the activation or inactivation of specific sets of genes through signal transduction cascades in the responding cells. When an inducer binds to its specific receptor on the surface of a cell, a signal transduction pathway leads to the activation of one or more transcription factors. Recall from [Key Concept 16.2](#) that these DNA-binding proteins regulate the expression of specific genes. You can follow this process in **Focus: Key Figure 19.8**, where the cell on the left is exposed to a high concentration of inducer. The inducer activates a transcription factor in the cytoplasm, which enters the nucleus to switch on the expression of a specific gene. The cell on the right is exposed to a lower concentration of the inducer, and as a result, gene expression is not activated.

focus: key figure

Figure 19.8 Induction The concentration of an inducer directly affects the degree to which a transcription factor is activated. The inducer acts by binding to a receptor on the target cell. This binding is followed by signal transduction involving transcription factor activation or translocation from the cytoplasm to the nucleus. In the nucleus it acts to stimulate the expression of genes involved in cell differentiation.

Q: Could differential expression of receptor genes result in differential gene expression through induction?

Differential gene transcription is a hallmark of cell differentiation

One well-studied example of cell differentiation is the conversion of undifferentiated muscle precursor cells into cells destined to form muscle ([Figure 19.9](#)). In the vertebrate embryo these cells come from a tissue layer called the *mesoderm. A key event in the commitment of these cells to become muscle is that they stop dividing. Indeed, in many parts of the embryo, *cell division and cell differentiation are mutually exclusive*. Cell signaling activates the gene for a transcription factor called [MyoD](#) (for myoblast-determining gene); this in turn activates the gene for p21, which is an inhibitor of the cyclin-dependent kinases (Cdk's) that normally stimulate the cell cycle at G1 (see [Figure 11.5](#)). Expression of the *p21* gene causes the cell cycle to stop, and other transcription factors then enter the picture so that differentiation can proceed. Interestingly, MyoD is also activated in the stem cells that are present in adult muscle, indicating a role of this transcription factor in the repair of muscle tissue as it gets damaged and worn out.

Figure 19.9 Transcription and Differentiation in the Formation of Muscle Cells
Production of the transcription factor MyoD is important in muscle cell differentiation.

MyoD The protein encoded by the *myoblast determining* gene. A transcription factor involved in the differentiation of myoblasts (muscle precursor cells).

Genes such as *myoD* that direct the most fundamental decisions in development (often by regulating other genes on other chromosomes) usually encode transcription factors. In some cases a single transcription factor can cause a cell to differentiate in a certain way. In others, complex interactions between genes and proteins determine a sequence of transcriptional events that leads to differentiation.

19.2 recap

Cell fate determination involves cytoplasmic segregation and induction. Cytoplasmic segregation is the unequal distribution of gene products in the egg, zygote, or early embryo. Induction occurs when one cell or tissue sends a chemical signal to another. Cell fate determination involves the activation of signal transduction pathways that lead to differential

gene expression. Differentiation involves selective gene expression, controlled at the level of transcription by transcription factors.

learning outcomes

You should be able to:

- Summarize how cytoplasmic segregation results in polarity in a fertilized egg and how this polarity affects cell fate determination.
 - Predict the consequences of manipulations of inducer-producing cells on development and differentiation.
 - Predict cellular, gene-expression, and phenotypic consequences of experimental manipulations of a transcription factor, such as MyoD concentrations on the development of muscle tissue.
-

1. How does cytoplasmic segregation result in polarity in a fertilized egg, and how does polarity affect cell fate determination?
 2. What would happen if an artificial, impermeable membrane were placed between the anchor cell and the underlying cells of the developing nematode? Explain your answer.
 3. Molecular biologists can attach genes to active promoters and insert them into cells. What would happen if *myoD* in undifferentiated myoblasts were inserted and overexpressed? Explain your answer.
-

You have seen how cell fate is determined and examined the roles of gene expression in cell fate determination and differentiation. We will now look at how gene expression affects differentiation and morphogenesis.

19.3 Gene Expression Determines Morphogenesis and Pattern Formation

Pattern formation is the process that results in the spatial organization of a tissue or organism. It is inextricably linked to morphogenesis, the creation of body form.

pattern formation In animal embryonic development, the organization of differentiated tissues into specific structures such as wings.

focus your learning

In development of flowering plants, organ identity genes encode transcription factors that result in the differentiation of floral organs.

Genetic and experimental lines of evidence support the floral organ determination model.

A cascade of gene expression events early in development establishes the differentiation of growth axes and organ formation in the fruit fly embryo.

Alterations of Hox genes can result in homeotic mutations.

Morphogen gradients provide positional information

During development, the key cellular question “What will I be?” is often answered in part by “Where am I?” Think of the cells in the developing nematode, which can develop into different parts of the vulva depending on their positions relative to the anchor cell (see [Figure 19.7](#)). This spatial “sense” is called **positional information**. Positional information often comes in the form of an inducer called a **morphogen**, which diffuses from one cell or group of cells to surrounding cells, setting up a concentration gradient (as you saw for LIN-3 in *C. elegans* vulval induction). There are two requirements for a signal to be considered a morphogen:

positional information In development, the basis of the spatial sense that induces cells to differentiate as appropriate for their location within the developing organism; often comes in the form of a morphogen gradient.

morphogen A diffusible substance whose concentration gradient determines a developmental pattern in embryonic animals and plants.

- It must directly affect target cells, rather than triggering a secondary signal that affects target cells.
- Different concentrations of the signal must cause different effects.

Developmental biologist Lewis Wolpert uses the “French flag model” to explain morphogens ([Figure 19.10A](#)). This model can be applied to the differentiation of the vulva in *C. elegans* and to the development of a vertebrate limb.

(A)

Each cell has the potential to develop as blue, white, or red.

The position of each cell is defined by the concentration of morphogen.

The position value is interpreted by the cells, which differentiate to form a pattern.

French flag

Figure 19.10 The French Flag Model (A) In the “French flag” model, a concentration gradient of a diffusible morphogen signals each cell to specify its position. **(B)** The zone of polarizing activity (ZPA) in the limb bud of the embryo secretes the morphogen Sonic *hedgehog* (Shh). Cells in the bud form different digits depending on the concentration of Shh.

The vertebrate limb develops from a paddle-shaped limb bud ([Figure 19.10B](#)). The cells that develop into different digits must receive positional information; if they do not, the limb will be totally disorganized—imagine a hand with only thumbs or only little fingers. A group of cells at the posterior base of the limb bud, just where it joins the body wall, is called the zone of polarizing activity (ZPA). The cells of the ZPA secrete a protein morphogen called Sonic hedgehog (Shh). Shh forms a gradient that determines the posterior-anterior (little finger to thumb) axis of the developing limb. In humans and other primates, the cells exposed to the highest dose of Shh form the little finger; those that receive the lowest dose develop into the thumb.

Expression of transcription factor genes determines organ differentiation in plants

Like animals, plants have organs—for example, leaves and roots. Many plants form flowers, and many flowers are composed of four types of organs: sepals, petals, stamens (male reproductive organs), and carpels (female reproductive organs). These floral organs occur in concentric

whorls, with groups of each organ type encircling a central axis. The sepals are on the outside and the carpels are on the inside ([Figure 19.11A](#)).

(A)

The four organs in a flower are determined by four groups of cells in the meristem.

(B)

(C)

The combinations of AA, AB, BC, and CC each act to stimulate expression of genes for a particular organ.

Figure 19.11 Organ Identity Genes in *Arabidopsis* Flowers (A) The four organs of a flower—carpels (yellow), stamens (green), petals (purple), and sepals (pink)—grow in whorls that develop from the floral meristem. (B) Floral organs are determined by three classes of organ identity genes whose polypeptide products combine in pairs to form transcription factors. (C) Combinations of polypeptide subunits in transcription factors activate gene expression for specific organs.

Activity 19.3 Genes and Development Simulation www.Life11e.com/ac19.3

In *Arabidopsis thaliana* (thale cress), flowers develop in a radial pattern around the shoot (stem and leaf) apex as it develops and elongates. At the shoot apex and in other parts of the plant where growth and differentiation occur (such as the root tip), there are groups of undifferentiated, rapidly dividing cells called **meristems**. Each flower begins as a floral meristem of about 700 undifferentiated cells arranged in a dome, and the four whorls develop from this meristem. How is the identity of a particular whorl determined? Three classes of genes called **organ identity genes** encode proteins that act in combination to produce specific whorl features (**Figure 19.11B and C**):

meristem [Gk. *meristos*: divided] Plant tissue made up of undifferentiated actively dividing cells.

organ identity genes In angiosperms, genes that specify the different organs of the flower. (Compare with homeotic genes.)

- Genes in class A are expressed in whorls 1 and 2 (which form sepals and petals, respectively).
- Genes in class B are expressed in whorls 2 and 3 (which form petals and stamens).
- Genes in class C are expressed in whorls 3 and 4 (which form stamens and carpels).

These genes encode transcription factors that are active as dimers, that is, proteins with two polypeptide subunits. The composition of the dimer determines which genes the transcription factor activates. For example, a dimer made up of two class A monomers activates transcription of the genes that make sepals; a dimer made up of A and B monomers results in petals, and so forth. A common feature of the A, B, and C proteins, as well as many other plant transcription factors, is a DNA-binding domain called the **MADS box**. The name “MADS” comes from the initials of four genes encoding proteins with this domain.

MADS box DNA-binding domain in many plant transcription factors that is active in development.

Two lines of experimental evidence support this model for floral organ determination:

- . *Loss-of-function mutations*: for example, a mutation in a class A gene results in no sepals or petals.

- . *Gain-of-function mutations*: for example, a promoter for a class C gene can be artificially coupled to a class A gene. In this case, the class A gene is expressed in all four whorls, resulting in only sepals and petals. In any organism, the replacement of one organ for another is called homeosis, and this type of mutation is a [homeotic mutation](#).

homeotic mutation Mutation in a homeotic gene that results in the formation of a different organ than that normally made by a region of the embryo.

Transcription of the floral organ identity genes is controlled by other gene products, including the LEAFY protein. The wild-type LEAFY protein is a transcription factor that stimulates expression of the class A, B, and C genes so that they produce flowers. Plants with loss-of-function mutations in the *LEAFY* gene make stems instead of flowers, with increased numbers of modified leaves called bracts. This finding has practical applications. It usually takes 6–20 years for a citrus tree to produce flowers and fruits. Scientists have made transgenic orange trees expressing the *LEAFY* gene coupled to a strongly expressed promoter. These trees flower and fruit years earlier than normal trees.

A cascade of transcription factors establishes body segmentation in the fruit fly

Perhaps the best-studied example of how morphogens determine cell fate is body segmentation in the fruit fly *Drosophila melanogaster*. The body segments of a fruit fly are different from one another. The adult fly has an anterior head (composed of several fused segments), three different thoracic segments, and eight abdominal segments at the posterior end. Each segment develops into different body parts: for example, antennae and eyes develop from head segments, wings from the thorax, and so on.

The life cycle of *Drosophila* from fertilized egg to adult takes about 2 weeks at room temperature. The egg hatches into a larva, which then forms a pupa, which finally is transformed into the adult fly. By the time a larva appears—about 24 hours after fertilization—there are recognizable segments. The thoracic and abdominal segments all look similar, *but the fates of*

their cells to become different adult segments have already been determined.

As in other organisms, fertilization in *Drosophila* leads to a rapid series of mitoses. However, the first 12 cycles of nuclear division are not accompanied by cytokinesis. So a multinucleate embryo forms instead of a multicellular embryo (the nuclei are brightly stained in the micrographs below):

With no cell membranes to cross, morphogens can diffuse easily within the embryo. We focus here on the determination events that occur in the first 24 hours after fertilization. We'll present what may appear to be a lot of detail but is really just an outline of the molecular events. In describing them, biologists are getting closer to answering a key question: How does a complex organism develop from a single cell?

Biologists used experimental genetics to describe the events leading to cell fate determination:

First, developmental mutations were identified. For example, a mutant strain might produce larvae with two heads or no segments.

Then the mutant flies were compared with wild-type flies, and the gene responsible for the developmental mistake, and the gene's protein product (if appropriate), were isolated.

Finally, experiments with the gene (making transgenic flies) and protein (injecting the protein into an egg or into an embryo) were done to confirm their roles in the proposed developmental pathway.

These approaches revealed an amazing cascade of gene expression events that result in the determination of each segment within 24 hours after fertilization. Several classes of genes are involved:

Maternal effect genes set up the major axes (anterior–posterior and dorsal–ventral) of the egg.

Segmentation genes determine the boundaries and polarity of each segment.

Hox genes determine which organ will be made at a given location.

maternal effect genes Genes coding for morphogens that determine the polarity of the egg and larva in fruit flies. Part of a developmental cascade that includes gap genes, pair rule genes, segment polarity genes, and Hox genes.

segmentation genes Genes that determine the number and polarity of body segments.

Hox genes Conserved homeotic genes found in vertebrates, *Drosophila*, and other animal

groups. Hox genes contain the homeobox and specify pattern and axis formation in these animals.

MATERNAL EFFECT GENES

Like the eggs and early embryos of sea urchins, *Drosophila* eggs and larvae are characterized by unevenly distributed cytoplasmic determinants (see [Figure 19.6](#)). These molecular determinants are the products of specific maternal effect genes that are transcribed in the cells of the mother's ovary. Two maternal effect genes called *bicoid* and *nanos* help determine the anterior–posterior axis of the egg. (The dorsal–ventral axis is determined by other maternal effect genes that will not be described here.)

The mRNAs for *bicoid* and *nanos* diffuse from the mother's cells and are passed to the egg by cytoplasmic bridges into what will be the anterior end of the egg. The *bicoid* mRNA is translated into Bicoid protein, a transcription factor that diffuses away from the anterior end, establishing a gradient in the egg cytoplasm ([Figure 19.12A](#)). Meanwhile, the egg's cytoskeleton transports the *nanos* mRNA from the anterior end of the egg, where it was deposited, to the posterior end, where it is translated ([Figure 19.12B](#)).

Figure 19.12 Concentrations of Bicoid and Nanos Proteins Determine the Anterior-Posterior Axis The anterior-posterior axis of *Drosophila* arises from gradients of the morphogens encoded by **(A)** *bicoid* and **(B)** *nanos*. Together, Bicoid and Nanos establish a concentration gradient of Hunchback **(C)**.

The actions of Bicoid and Nanos establish a gradient of yet another protein, called Hunchback, which determines the anterior and posterior ends of the embryo. Initially, the *hunchback* mRNA is evenly distributed in the embryo, but Nanos inhibits its translation, thus preventing Hunchback protein accumulation at the posterior end of the embryo ([Figure 19.12C](#)).

Meanwhile, at the anterior end of the embryo, Bicoid stimulates increased transcription of the *hunchback* gene, thus increasing the amount of *hunchback* mRNA (and thus Hunchback protein) and further strengthening the Hunchback gradient.

How did biologists elucidate these pathways? Let's look at the experimental approaches used in this case.

Females that are homozygous for a particular *bicoid* mutation produce larvae with no head and no thorax; thus the Bicoid protein must be needed for the anterior structures to develop.

If the eggs of these *bicoid* mutant flies are injected at the anterior end with cytoplasm from the anterior region of a wild-type egg, the injected eggs develop into normal larvae. This experiment also shows that the Bicoid protein is involved in the development of anterior structures.

If cytoplasm from the anterior region of a wild-type egg is injected into the posterior region of another egg, anterior structures develop there. The degree of induction depends on how much cytoplasm is injected.

Eggs from homozygous *nanos* mutant females develop into larvae with missing abdominal segments.

If cytoplasm from the posterior region of a wild-type egg is injected into the posterior region of a *nanos* mutant egg, it will develop normally.

The events involving *bicoid*, *nanos*, and *hunchback* begin before fertilization and continue after it, during the multinucleate stage, which lasts a few hours. At this stage the embryo looks like a bunch of indistinguishable nuclei under the light microscope. But a lot is going on at the molecular level, as cell fates have already begun to be determined. After the anterior and posterior ends have been established, the next step in pattern formation is the determination of segment number and locations.

SEGMENTATION GENES

These genes determine the number and polarity of the *Drosophila* larval segments and are expressed when there are about 6,000 nuclei in the embryo (about 3 hours after fertilization). Three classes of segmentation genes act one after the other to regulate finer and finer details of the segmentation pattern:

- **Gap genes** organize broad areas along the anterior–posterior axis. Mutations in gap genes result in gaps in the body plan—the omission of several consecutive larval segments.
- **Pair rule genes** divide the embryo into units of two segments each. Mutations in pair rule genes result in embryos missing every other segment.
- **Segment polarity genes** determine the boundaries and anterior–posterior organization of the individual segments. Mutations in segment polarity genes can result in segments in which posterior structures are replaced by reversed (mirror-image) anterior structures.

gap genes In *Drosophila* development, segmentation genes that define broad areas along the anterior–posterior axis of the early embryo. Part of a developmental cascade that includes maternal effect genes, pair rule genes, segment polarity genes, and Hox genes.

pair rule genes In *Drosophila* (fruit fly) development, segmentation genes that divide the early embryo into units of two segments each. Part of a developmental cascade that includes maternal effect genes, gap genes, segment polarity genes, and Hox genes.

segment polarity genes In *Drosophila* (fruit fly) development, segmentation genes that determine the boundaries and anterior-posterior organization of individual segments. Part of a

developmental cascade that includes maternal effect genes, gap genes, pair rule genes, and Hox genes.

The expression of these genes is sequential ([Figure 19.13](#)). The products of the gap genes activate pair rule genes, and the pair rule gene products activate segment polarity genes. By the end of this cascade, nuclei throughout the embryo “know” which segment they will be part of in the adult fly.

Figure 19.13 A Gene Cascade Controls Pattern Formation in the *Drosophila* Embryo

(A) Maternal effect genes induce gap, pair rule, and segment polarity genes—collectively referred to as segmentation genes. **(B)** Expression of two gap genes, *hunchback* (orange) and *Krüppel* (green), overlaps; both genes are transcribed in the yellow area. **(C)** The pair rule gene *fushi tarazu* is transcribed in the dark blue areas. **(D)** The segment polarity gene *engrailed* (bright green) is seen here at a slightly more advanced stage than is depicted in (A). By the end of this cascade, a group of nuclei at the anterior of the embryo, for example, is determined to become the first head segment in the adult fly.

The next set of genes in the cascade determines the form and function of each segment.

HOX GENES Hox

(for “Homeobox”) genes encode a family of transcription factors that are expressed in different combinations along the length of the embryo, and help determine cell fate within each segment. Hox gene expression tells the cells of a segment in the head to make eyes, those of a segment in the thorax to make wings, and so on. The *Drosophila* Hox genes occur in two clusters on chromosome 3, in the same order as the segments whose function they determine ([Figure 19.14](#)). By the time the fruit fly larva hatches, its segments are completely determined. Hox genes are shared by all animals and are homeotic genes—that is, a mutation in a Hox gene can result in one organ being replaced by another.

Figure 19.14 Hox Genes in *Drosophila* Determine Segment Identity Two clusters of Hox genes on chromosome 3 (center) determine segment function in the adult fly (top). These genes are expressed in the embryo (bottom) long before the structures of the segments actually appear.

In *Drosophila*, the maternal effect genes, segmentation genes, and Hox genes interact to “build” a larva step by step, beginning with the unfertilized egg. How do we know that the Hox genes determine segment identity? A clue comes from homeotic mutations. A mutation in the Hox gene *Antennapedia* causes legs to grow on the head in place of antennae.

When another Hox gene—*Ultrabithorax*—is mutated, an extra pair of wings grows in a thoracic segment where wings do not normally occur. So the normal (wild-type) functions of Hox genes must be to “tell” a segment what organ to form.

The *Antennapedia* and *Ultrabithorax* genes both encode transcription factors and have a common 180 base-pair sequence called the [homeobox](#). The homeobox encodes a 60 amino acid sequence called the [homeodomain](#). The homeodomain recognizes and binds to a specific DNA sequence in the promoters of its target genes. This protein domain is found in transcription factors that regulate development in many other animals with an anterior–posterior axis. We will discuss the evolutionary significance of these common pathways for development in the next section.

homeobox 180-base-pair segment of DNA found in certain homeotic genes. A specific sequence within the homeobox—the homeodomain—regulates the expression of other genes and through this regulation controls large-scale developmental processes. (See homeotic genes.)

homeodomain See homeobox.

19.3 recap

Cascades of transcription factors govern pattern formation and the subsequent development of animal and plant organs. Often these transcription factors create or respond to morphogen gradients. In plants, cell fate is often determined by MADS box genes; in animal embryos, cell fate is determined in part by Hox genes.

learning outcomes

You should be able to:

- Summarize the function of floral organ identity genes.
- Use an example to explain how organ identity genes work in combination to produce flower organs.
- Determine the appropriate homeotic mutation to use to generate flowers with particular alterations in their organs.
- Summarize how mutations were used to identify organ identity genes.
- Predict the consequences of altering *nanos* expression for the developing fly embryo.

1. What are organ identity genes, and how are they identified by mutations? How do they act in combination to produce different organs in a developing plant?
2. If you wanted a rose plant to make flowers with only petals, what kind of homeotic mutation would you seek in the rose genome?

3. Biotechnology enables the insertion of foreign genes into host cells along with promoters that maximize its expression (see the discussion of expression vectors in [Key Concept 18.5](#)). What would happen if *nanos* were inserted and over-expressed at the anterior end of the *Drosophila* embryo?

We have described some of the details of the role of gene expression in the control of development in two model organisms—*Arabidopsis* and *Drosophila*. Both involve genes whose expression as transcription factors control the expressions of other genes that result in differentiation and organ formation. Are these mechanisms basic to developmental biology, and have they been conserved through evolution?

19.4 Changes in Gene Expression Underlie the Evolution of Development

The discovery of the genes that control the development of *Drosophila* provided biologists with tools to investigate the development of other organisms. For example, when scientists used homeobox DNA as a hybridization probe (see [Key Concept 14.4](#)) to search for similar genes elsewhere, they found the homeobox sequence in many genes in other organisms. This and other discoveries that followed revealed similarities in the molecular events underlying morphogenesis in organisms ranging from flies to fish to mammals. These findings suggested that just as the forms of organisms evolved through descent with modification from a common ancestor, so did the molecular mechanisms that produce those forms. Biologists started to ask new questions about the interplay between evolutionary and developmental processes, a field of study called [evolutionary developmental biology](#), or **evo-devo**.

evolutionary developmental biology (evo-devo) The study of the interplay between evolutionary and developmental processes, with a focus on the genetic changes that give rise to novel morphology. Key concepts of evo-devo include modularity, genetic toolkits, genetic switches, and heterochrony.

focus your learning

Common developmental pathways are involved in embryonic development of many animals, such as the formation of eyes in both insects and vertebrates.

DNA sequences and regulatory proteins common in developmental pathways comprise a “toolkit.” Genetic switches control how the toolkit is expressed.

Heterochrony has significant importance, as illustrated by the extreme length of a giraffe’s neck.

As organisms have evolved, there are changes in where (heterotopy), when (heterochrony), and to what extent (heterometry) developmental genes are expressed.

Spatial differences in the expression of a developmental gene are known as heterotopy.

What is evo-devo?

The basic principles of evo-devo are:

Organisms share similar molecular mechanisms for development that include a “toolkit” of regulatory molecules that control the expression of genes.

Toolkit regulatory molecules are able to act independently in different tissues and regions of the body, enabling modular evolutionary change.

Developmental differences can arise from changes in the timing of regulatory molecule action, the location of its action, or the quantity of its action.

Differences among species can arise from alterations in the expression of developmental genes.

Developmental changes can arise from environmental influences on developmental processes.

As you saw earlier in the chapter, the development of a multicellular organism from a fertilized egg involves sequential gene expression. The complexities for each organism led biologists to predict that the pathways that make a mouse, for example, would be very different from those that make a fruit fly. But they were in for a surprise. It turns out that the regulatory genes that control the formation of organs are similar in very different organisms.

Developmental genes in distantly related organisms are similar

About a dozen major ***kinds of eyes** are found among the different animals, including the camera-like eyes of humans and the compound eyes of insects. Although the eyes of insects and vertebrates evolved independently, a remarkable discovery showed that common developmental pathways are involved in the embryonic formation of eyes in both groups.

More than a century ago, a mutation was described in *Drosophila* called *eyeless*, with a phenotype of—you guessed it—no eyes.

This mutation remained a laboratory curiosity for many decades until its molecular nature was elucidated in the 1990s. Swiss developmental biologists Rebecca Quiring and Walter Gehring isolated the protein product of the wild-type version of the *eyeless* gene, which they determined was a transcription factor that controls the expression of genes responsible for eye development. How did they know this? By making recombinant DNA constructs that allowed the wild-type *eyeless* gene to be expressed in different embryonic tissues of transgenic flies, they were able to produce flies with extra eyes on various body parts such as the legs, the antennae, and under the wings.

The big surprise came when the biologists sequenced the *eyeless* gene and used computers to query a database of genes with known sequences. The *eyeless* gene sequence was similar to that of the *Pax6* gene in mice; *Pax6*, when mutated, leads to the development of abnormally small eyes. Could the extremely different eyes of flies and mice be variations on a common developmental theme? To test for functional similarity between the insect and mammalian genes, the biologists repeated their experiments on flies, but using the mouse *Pax6* gene instead of the fly *eyeless* gene. Once again, eyes developed at various sites on the transgenic flies. Thus a gene whose expression normally leads to the development of a mammalian eye now led to the development of the very different insect eye.

We have to look very far back in evolutionary time for a common ancestor of fruit flies and mice. Yet the *eyeless* and *Pax6* genes contain sequences that are highly conserved, not only in these two species but in others as well. Biologists call such genes **homologous**, meaning that they evolved from a gene present in a common ancestor.

homologous pair A pair of matching chromosomes made up of a chromosome from each of the two sets of chromosomes in a diploid organism.

In recent years a large number of homologous genes (the regulatory “toolkit”) have been shown to control development in distantly related species. For example, the fruit fly homeotic

genes such as *Antennapedia* and *bithorax* are similar to mouse (and human) genes that play similar developmental roles. This discovery indicates that the positional information controlled by these genes has been conserved, even as the structures formed at each position have changed. Remarkably, these genes are arranged along a chromosome in both fruit fly and mouse in the same order as they are expressed along the anterior–posterior axis of the embryos ([Figure 19.15](#)). These and other examples have led biologists to the idea that certain developmental mechanisms are controlled by specific sequences comprising a **genetic toolkit**, the contents of which have been changed and reshuffled over the course of evolutionary time to produce the amazing diversity of plants, animals, and other organisms that we see today.

Figure 19.15 Regulatory Genes Show Similar Expression Patterns Homologous genes encoding similar transcription factors are expressed in similar patterns along the anterior-posterior axes of both insects and vertebrates. The mouse (and human) Hox genes are present in multiple copies; this prevents a single mutation from having drastic effects.

genetic toolkit A set of developmental genes and proteins that is common to most animals and is hypothesized to be responsible for the evolution of their differing developmental pathways.

One way that the toolkit can change is through ***gene duplication**. As noted in [Figure 19.14](#), *Antennapedia* and *bithorax* are not just single genes, but gene clusters, with each gene slightly different from the others. When we described gene families in [Key Concept 17.3](#), we observed that each member of the family evolved from a single, ancestral gene. So it is with these developmental genes. Through duplication and subsequent mutation, the Hox genes diverged to encode different structures in different segments:

Genetic switches govern how the genetic toolkit is used

Developmental modules based on a common set of genetic instructions can evolve separately within a species because **genetic switches** control how the toolkit is used. These switches include:

genetic switches Mechanisms that control how the genetic toolkit is used, such as promoters and the transcription factors that bind them. The signal cascades that converge on and operate these switches determine when and where genes will be turned on and off.

gene promoters and the ***transcription factors** that bind to promoters.

enhancers and repressors that can modulate the interactions of transcription factors and promoters.

signaling molecules that activate pathways or gene expression.

signal transduction components that mediate signaling and its effects.

Multiple switches control each gene, creating different expression patterns in different locations. In this way, elements of the genetic toolkit can be involved in multiple developmental processes and still allow individual modules to develop and evolve independently.

Animation 19.4 **Modularity** www.Life11e.com/a19.4

During evolution, changes in the functions of genetic switches have led to changes in the forms and functions of organisms. To illustrate this, let's look at the development of wings in *Drosophila* and other insects. *Drosophila* species are members of the insect group Diptera, which means “two wings”—that is, they have a single pair of wings, whereas most insects have two pairs of wings (i.e., four wings). The single pair of wings of dipterans develops on the second thoracic segment, where the Hox gene *Antennapedia* (*Antp*) is expressed. *Antp* is also expressed in the third thoracic segment, but in that segment a pair of balancing organs called halteres develops in dipterans. A critical difference between thoracic segments 2 and 3 is that another Hox gene, *Ultrabithorax* (*Ubx*), is expressed along with *Antp* in segment 3 (**Figure 19.16**). *Ubx* represses *Antp* function in dipterans. If *Ubx* is inactivated by mutation, a second pair of wings forms in thoracic segment 3, as is typical of many other insect groups. Thus some major morphological differences among groups of animals can result from relatively small changes in gene expression.

Figure 19.16 Segments Differentiate under Control of Genetic Switches The binding of a single protein, Ultrabithorax (Ubx), determines whether a thoracic segment produces full wings or halteres.

Q: What would happen if *Ubx* was genetically engineered to be expressed in all thoracic segments in a butterfly embryo?

Modularity allows for differences in the patterns of gene expression

The modularity of development means that the molecular pathways for developmental processes such as organ formation operate independently from one another. For instance, the *Antennapedia* mutant fly shown on p. 414 grew a leg where an antenna should be, but the rest of the segments formed structures normally. Modularity allows the timing and position of a developmental process to change without changing the whole organism. Several patterns have been noted.

HETEROMETRY

A striking example of **heterometry** (“different measure”) is beak development in Galápagos finches, in which the beaks of some species are large and robust for cracking seeds and in other species are thin and long for probing for food. When he visited these islands, Charles Darwin wrote that “seeing this gradation and diversity of structure in one small intimately related group of birds, one might really fancy that from an original paucity of birds in this archipelago, one species had been taken and modified for different ends.”

heterometry [Gk. different measure] Alteration in the level of gene expression, and thus in the amount of protein produced, during development, contributing to the evolution of different

phenotypes in the adult. (Contrast with heterochrony, heterotypy.)

Darwin had no idea of the genetic basis for such modification. Now we do. Beak shapes are evident when birds hatch from their eggs, so they must be determined during development. The beak develops from tissues at the anterior of the embryo that will form the facial bones. Cell divisions in this embryonic tissue are controlled by signaling proteins, one of which is called bone morphogenetic protein 4 (BMP4); another is the protein calmodulin. If BMP4 is present early and in large amounts, the beak becomes broad and deep. If calmodulin is present early and in large amounts, the beak grows longer and thinner (Figure 19.17). Thus beak structure is affected by changes in protein production.

Figure 19.17 Heterometry and the Beaks of Finches (A) Bird beaks can be measured in three dimensions (length, width, and depth) for the purpose of comparing different species. **(B)** Among Galapagos finches, mutations resulting in different patterns of BMP4 and calmodulin (CaM) expression may be responsible for the different species' beak sizes and shapes, which are suited for exploiting different types of food.

HETEROCHRONY

The evolution of the giraffe's neck provides an example of [heterochrony](#) ("different time"). Giraffes, like all mammals except manatees and sloths, have seven cervical (neck) vertebrae. So giraffes did not get longer necks by adding more vertebrae. However, the cervical vertebrae of giraffes are much longer than those of other mammals ([Figure 19.18](#)).

heterochrony [Gk. different time] Alteration in the timing of developmental events, contributing to the evolution of different phenotypes in the adult. (Contrast with heterometry, heterotypy.)

Figure 19.18 Heterochrony in the Development of a Longer Neck There are seven vertebrae in the neck of the giraffe **(A)** and human **(B; not to scale)**. But the vertebrae of the giraffe are much longer (25 cm compared with 1.5 cm) because during development, growth continues for a longer period of time. This timing difference is called heterochrony.

Bone growth in mammals is the result of the proliferation of cartilage-producing cells called chondrocytes. Bone growth is stopped by a genetic signal that results in apoptosis, or cell death, of chondrocytes and calcification of the bone matrix (see [Key Concept 47.3](#)). In giraffes this signaling process is delayed in the cervical vertebrae, so that these vertebrae grow longer. Thus the evolution of longer necks resulted from *changes in the timing* of expression of the genes that

control bone formation.

HETEROTOPY

Spatial differences in the expression of a developmental gene are known as [heterotopy](#) (“different place”), exemplified by the different development of feet in ducks and chickens. The feet of all bird embryos have webs of skin that connect their toes. This webbing is retained in adult ducks (and other aquatic birds) but not in adult chickens (and other nonaquatic birds). The loss of webbing is controlled by the BMP4 signaling protein, which as we have noted is also involved in beak development (another example of use of a common genetic toolkit to produce different kinds of change).

heterotopy [Gk. different place] Spatial differences in gene expression during development, controlled by developmental regulatory genes and contributing to the evolution of distinctive adult phenotypes.

BMP4 protein induces the cells that produce webbing to undergo apoptosis and thus eliminate the webbing between the toes. The hindlimbs of both duck and chicken embryos express the *BMP4* gene in the webbing between the toes; however, they differ in expression of the *Gremlin* gene, which encodes a protein that inhibits *BMP4* expression ([Figure 19.19](#)). In ducks, but not in chickens, *Gremlin* is expressed in the webbing cells and Gremlin protein inhibits *BMP4* expression. With no BMP4 protein to stimulate apoptosis, a webbed foot develops. If chick hindlimbs are experimentally exposed to Gremlin during development, the adult chicken will have ducklike webbed feet.

Figure 19.19 Heterotopy in Gremlin Expression Correlates with Changes in

Hindlimb Structure The left column of photos shows foot development in a chicken; the right column shows foot development in a duck. Gremlin protein in the webbing of the duck foot inhibits BMP4 signaling, thus preventing the embryonic webbing from undergoing apoptosis.

Q: What do you predict would happen if you blocked the expression of Gremlin in the feet of duck embryos?

19.4 recap

A genetic toolkit consisting of highly conserved regulatory genes governs pattern formation in multicellular organisms. Genetic toolkit genes act independently among modules of a developing embryo. The expression of these developmental genes can differ among species in various ways, often resulting in major morphological differences. They can differ in amount of expression (heterometry), in the timing of expression (heterochrony), or in the location of expression (heterotopy).

learning outcomes

You should be able to:

- Use a specific example to defend the claim “Genes controlling development are highly conserved.”
- Provide plausible evolutionary explanations for cases where different populations or closely related species differ in genetic switches.
- Interpret experimental results to assess the role of BMP4 in beak development.

1. How does the story of the eye-determining genes *Pax6* and *eyeless* support the claim that genes controlling development are highly conserved?
2. In a series of experiments on chick embryos, researchers applied different concentrations of BMP4 to the embryos’ beak growth region. They measured the size of the beak cartilage at a later stage of development. Based on the data in the table below, what could you conclude about the role of BMP4 in beak growth?

Amount of BMP4	Cartilage diameter (mm)
None (control)	0.5
0.1 unit	0.7
0.3 unit	1.0
1.0 unit	1.8

3. *Plasmodium vivax* is a protist that causes a form of malaria. When *P. vivax* enters the blood, it attaches to a glycoprotein on the red blood cells. Some human populations in Africa are immune to *P. vivax* because they lack this particular glycoprotein on their red blood cells. In a variety of tissues the transcription of this glycoprotein is under the influence of enhancers, and the enhancer that is normally expressed in red blood cell precursors is mutated in individuals immune to this form of malaria. What does this case illustrate in evolutionary developmental terms?

You have seen how the genetic toolkit guides morphogenesis in individual organisms, and how differences in genetic switches contribute to differences among species. Now we discuss the roles that some of these same tools play in the evolution of new forms and new species.

19.5 Developmental Gene Changes Can Shape Evolution

The genetic switches that allow different structures to develop in different regions of the embryo can also give rise to major morphological differences among species. Changes in timing and position of a genetic switch (e.g., *Gremlin* expression) can generate morphological changes (e.g., webbed or unwebbed feet) that can be acted on by natural selection.

focus your learning

A major developmental change can be caused by an alteration in a regulatory molecule.

Similar changes in gene expression in isolated populations of organisms can lead to the same evolutionary result, a process called parallel evolution.

French geneticist François Jacob suggested that evolution works like a tinker, assembling new structures by combining and modifying the available materials, and not like an engineer, who is free to develop dramatically different designs (a jet engine to replace a propeller-driven engine, for example). You have seen that morphological evolution is not usually governed by the acquisition of radically new genes, but proceeds primarily by “tinkering” with the expression patterns of existing genes. Thus developmental genes and their expression constrain evolution in two major ways:

- . Nearly all evolutionary innovations are modifications of previously existing structures.
- . The basic set of regulatory genes that control development is broadly conserved, changing only slowly over the course of evolution.

Mutations in developmental genes can cause major morphological changes

Sometimes a major developmental change is caused by an alteration in the regulatory molecule itself rather than a change in where, when, or how much it is expressed. The gene that controls the number of legs in arthropods offers an excellent example. Arthropods all have head, thoracic, and abdominal regions with variable numbers of segments. Insects, such as *Drosophila*, have three pairs of legs on their three thoracic segments, whereas centipedes have many legs on both thoracic and abdominal segments. All arthropods express a gene called *Distal-less (Dll)* that controls segmental leg development. In insects, *Dll* expression is repressed in abdominal segments by the Hox gene *Ubx*. *Ubx* is expressed in the abdominal segments of all arthropods, but it has different effects in different species. In centipedes, *Ubx* is co-expressed with *Dll* to promote the formation of legs. During the evolution of insects, a mutation in the *Ubx* gene sequence resulted in a modified *Ubx* protein that *represses Dll* expression in abdominal segments. A phylogenetic tree of arthropods shows that this change in *Ubx* occurred in the ancestor of insects, at the same time that abdominal legs were lost ([Figure 19.20](#)).

Figure 19.20 A Mutation in a Hox Gene Changed the Number of Legs in Insects

In the insect lineage (blue box) of the arthropods, a change to the *Ubx* gene resulted in a protein that inhibits the *Dll* gene, which is required for legs to form. Because insects express this modified *Ubx* gene in their abdominal segments, no legs grow from these segments. Other arthropods, such as centipedes, produce an unmodified *Ubx* protein and do grow legs from their abdominal segments.

Q: What do you predict the phenotype would be if you genetically engineered *Drosophila* to express the centipede version of *Ubx*?

Conserved developmental genes can lead to parallel evolution

The existence of highly conserved developmental genes makes it likely that similar traits will evolve repeatedly, especially among closely related species. This process is known as **parallel evolution**, and a good example is provided by a small fish, the three-spined stickleback (*Gasterosteus aculeatus*). Sticklebacks are widely distributed throughout the Atlantic and Pacific oceans; they are also found in many freshwater lakes and rivers. Marine sticklebacks spend most of their lives at sea but return to fresh water to breed. However, freshwater populations that are isolated in lakes never encounter salt water.

parallel evolution The repeated evolution of similar traits, especially among closely related species; facilitated by conserved developmental genes.

Genetic evidence shows that freshwater populations have arisen from marine populations many times, and independently. Marine sticklebacks have structures that protect them from predatory marine fish; these are bony plates and well-developed pelvic bones with pelvic spines that lacerate the mouths of predators. Freshwater sticklebacks do not face such predatory dangers; their body armor is greatly reduced, and their dorsal and pelvic spines are shorter or even lacking (**Figure 19.21**).

Figure 19.21 Parallel Phenotypic Evolution in Sticklebacks A developmental gene, *Pitx1*, encodes a transcription factor that stimulates the production of plates and spines. This gene is active in marine sticklebacks, but mutated and inactive in various freshwater populations of the fish. The fact that this mutation is found in geographically distant and isolated freshwater populations is evidence for parallel evolution.

The differences between marine and freshwater sticklebacks are not induced by environmental conditions. Marine species reared in fresh water still grow armor and spines. The differences are due to the expression of a developmental regulatory gene, *Pitx1*. *Pitx1* codes for a transcription factor normally expressed in regions of the developing embryo that in marine sticklebacks form the head, trunk, tail, and pelvis. However, in separate and long-isolated populations of freshwater sticklebacks from Canada, the United Kingdom, the United States, and Iceland, the *Pitx1* gene is no longer expressed in the pelvis, and spines do not develop. This same change in regulatory gene expression has evolved to produce similar phenotypic changes in several independent populations, and is thus a good example of parallel evolution.

19.5 recap

A mutation in a gene controlling a developmental pathway can result in major changes in morphology, which provide the raw material for evolution by natural selection. The conservation of many developmental regulatory genes makes it likely that similar traits will evolve repeatedly.

learning outcomes

You should be able to:

- Summarize how mutations in developmental genes have led to diversity in arthropod body plans.
- Show how differences between marine and freshwater sticklebacks exemplify parallel evolution via changes in gene regulation.

1. How have diverse body forms in arthropods evolved by means of mutations in developmental genes?
2. How do the differences between marine and freshwater sticklebacks exemplify parallel evolution via changes in gene regulation?

Many novel traits have arisen during the course of evolution, but most of them failed to persist beyond even a single generation. [Part Six](#) of this book will examine the processes of evolution—the powerful forces that influence the survival and reproductive success of various life forms. You will see how different adaptations become prevalent in different environments, resulting in the extraordinary diversity of life on Earth today, which we will describe in further detail in [Part Seven](#).

investigatinglife

QA What are the potential uses of stem cells?

A procedure has been developed to isolate stem cells from human patients in the operating room. Large quantities of stem cells from fat can be derived from the cosmetic procedure known as liposuction. These stem cells are stored at very low temperatures and become viable when they are warmed up. Stem cells retrieved from liposuction procedures have been used to repair tissues. For example, they have been used in stem cell transplantation after surgery for breast cancer. In other cases, they have been used to help heal skull fractures. Mesenchymal cells from fat as well as bone marrow have been used to help the healing of connective tissues such as muscles and tendons in athletic injuries as well.

Future directions

Millions of people have type 1 diabetes, whereby β (beta) cells in the pancreas do not make the hormone insulin. These people must take insulin as a medication, made from recombinant DNA technology (see [Key Concept 18.5](#)). However, the timing and regulation of the amount of insulin taken can be problematic, and symptoms often persist. Supplying a patient with functional β cells could potentially cure type 1 diabetes. Both embryonic and induced human pluripotent stem cells have been shown in lab experiments to make insulin. Moreover, they also regulate insulin release in response to environmental conditions and restore normal function when transplanted into the pancreas of diabetic mice. clinical trials in diabetic humans are planned.

In the United States, the only clinical use of stem cells for humans that has been rigorously tested and approved by the government is hematopoietic (bone marrow) transplantation. Nevertheless, clinics offering stem cell treatments for many diseases are springing up in South America, Asia, and the United States (without government approval), treating growing numbers of patients each year. While claims of cures abound, more research is required to establish the efficacy and safety of stem cell therapy.

► 19.1 The Four Major Processes of Development Are Determination, Differentiation, Morphogenesis, and Growth

- A multicellular organism begins its development as an embryo. Embryogenesis results in a new organism with a body plan characteristic of its species. **Review Figure 19.1, Activity 19.1**
- The processes of development are [determination](#), [differentiation](#), [morphogenesis](#), and [growth](#).

determination In development, the process whereby the fate of an embryonic cell or group of cells (e.g., to become epidermal cells or neurons) is set (becomes **determined**).

differentiation The process whereby originally similar cells follow different developmental pathways; the actual expression of determination.

morphogenesis (more' fo jen' e sis) [Gk. *morphe*: form + *genesis*: origin] The development of form; the overall consequence of determination, differentiation, and growth.

growth An increase in the size of the body and its organs by cell division and cell expansion.

- Differential gene expression is responsible for the differences among cell types. [Cell fate](#) is determined by environmental factors, such as the cell's position in the embryo, as well as by intracellular influences. **Review Figure 19.2, Activity 19.2**

cell fate The type of cell that an undifferentiated cell in an embryo will become in the adult.

- Over the course of development, embryo cells decrease in [cell potency](#). [Totipotent](#) cells (such as a zygote) are capable of forming every cell type in the adult body. [Pluripotent](#) cells can give rise to most cell types, [multipotent](#) cells to several cell types, and [unipotent](#) cells to only one cell type.

cell potency In multicellular organisms, an undifferentiated cell's potential to become a cell of a specific type. (See multipotent, pluripotent, totipotent.)

totipotent [L. *toto*: whole, entire + *potens*: powerful] Possessing all the genetic information and other capacities necessary to form an entire individual. (Contrast with multipotent, pluripotent, unipotent.)

pluripotent [L. *pluri*: many + *potens*: powerful] Having the ability to form all of the cells in the body. (Contrast with multipotent, totipotent, unipotent.)

multipotent Having the ability to differentiate into a limited number of cell types. (Contrast with pluripotent, totipotent, unipotent.)

unipotent An undifferentiated cell that is capable of becoming only one type of mature cell. (Contrast with totipotent, multipotent, pluripotent.)

- The ability to create clones from differentiated cells demonstrates the principle of

[genomic equivalence](#). **Review** [Figures 19.3](#), [19.4](#)

genomic equivalence All somatic cells in a complex organism have the entire genome of that organism.

- [Stem cells](#) produce daughter cells that differentiate when provided with appropriate intercellular signals. Some multipotent stem cells in the adult body can differentiate into a limited number of cell types to replace dead cells and maintain tissues. **Review** [Investigating Life: Stem Cell Therapy](#)

stem cell In animals, an undifferentiated cell that is capable of continuous proliferation. A stem cell generates more stem cells and a large clone of differentiated progeny cells. (See also embryonic stem cell.)

- [Embryonic stem cells](#) ([ESCs](#)) are pluripotent and can be cultured in the laboratory. Under suitable environmental conditions, these cells can differentiate into almost any tissue type. [Induced pluripotent stem cells](#) ([iPS cells](#)) have similar characteristics, making possible technologies designed to replace cells or tissues damaged by injury or disease. **Review** [Figure 19.5](#), [Animation 19.1](#)

embryonic stem cell (ESC) A pluripotent cell in the blastocyst.

ESC See embryonic stem cell.

induced pluripotent stem cells (iPS cells) Multipotent or pluripotent animal stem cells produced from differentiated cells in vitro by the addition of several genes that are expressed.

► 19.2 Gene Expression Differences Determine Cell Fate and Cell Differentiation

- [Cytoplasmic segregation](#)—the unequal distribution of [cytoplasmic determinants](#) in the egg, zygote, or early embryo—can establish [polarity](#) and lead to cell fate determination. **Review** [Figure 19.6](#), [Animation 19.2](#)

cytoplasmic segregation The asymmetrical distribution of cytoplasmic determinants in a developing animal embryo.

cytoplasmic determinants In animal development, gene products whose spatial distribution may determine such things as embryonic axes.

polarity (1) In chemistry, the property of unequal electron sharing in a covalent bond that defines a polar molecule. (2) In development, the difference between one end of an organism or structure and the other.

- [Induction](#) is a process by which embryonic animal tissues direct the development of neighboring cells and tissues by secreting chemical signals, called inducers. **Review** [Figure 19.7](#)

induction In embryonic development, the process by which a factor produced and secreted by certain cells determines the fates of other cells.

- Inducers act through signaling pathways to determine cell fate. **Review Focus: Key Figure 19.8**
- Differential gene expression results in cell differentiation. Transcription factors are especially important in regulating gene expression during differentiation. **Review Figure 19.9**

▶ 19.3 Gene Expression Determines Morphogenesis and Pattern Formation

- **Pattern formation** is the process that results in the spatial organization of a tissue or organism.

pattern formation In animal embryonic development, the organization of differentiated tissues into specific structures such as wings.

- Both plants and animals use **positional information** as a basis for pattern formation. Positional information usually comes in the form of a signal called a **morphogen**. Different concentrations of the morphogen cause different effects. **Review Figure 19.10**

positional information In development, the basis of the spatial sense that induces cells to differentiate as appropriate for their location within the developing organism; often comes in the form of a morphogen gradient.

morphogen A diffusible substance whose concentration gradient determines a developmental pattern in embryonic animals and plants.

- Sepals, petals, stamens, and carpels form in plants as a result of combinatorial interactions between transcription factors encoded by **organ identity genes**. **Review Figure 19.11, Activity 19.3**

organ identity genes In angiosperms, genes that specify the different organs of the flower. (Compare with homeotic genes.)

- In the fruit fly *Drosophila melanogaster*, a cascade of transcriptional activation sets up the axes of the embryo, the development of the segments, and finally the determination of cell fate in each segment. The cascade involves the sequential expression of **maternal effect genes, gap genes, pair rule genes, segment polarity genes**, and **Hox genes**. **Review Figures 19.12, 19.13, Animation 19.3**

Hox genes Conserved homeotic genes found in vertebrates, *Drosophila*, and other animal groups. Hox genes contain the homeobox and specify pattern and axis formation in these animals.

- Hox genes help determine cell fate in the embryos of all animals. The **homeobox** is a DNA sequence found in Hox genes and other genes that code for transcription factors. The sequence of amino acids encoded by the homeobox is called the **homeodomain**. **Review Figure 19.14**

homeobox 180-base-pair segment of DNA found in certain homeotic genes. A specific sequence within the homeobox—the homeodomain—regulates the expression of other genes and through this regulation controls large-scale developmental processes. (See homeotic genes.)

► 19.4 Changes in Gene Expression Underlie the Evolution of Development

- **Evolutionary developmental biology**, or **evo-devo**, is the study of the evolutionary aspects of development. This field focuses on the molecular mechanisms that underlie the development of phenotypic diversity.

evolutionary developmental biology (evo-devo) The study of the interplay between evolutionary and developmental processes, with a focus on the genetic changes that give rise to novel morphology. Key concepts of evo-devo include modularity, genetic toolkits, genetic switches, and heterochrony.

- Similarities in the basic mechanisms of development between widely divergent organisms reflect common ancestry.
- Genes encoding transcription factors and other regulatory proteins that govern pattern formation in the developing bodies of multicellular organisms comprise what is called a **genetic toolkit**. These regulatory genes have been highly conserved throughout evolution. **Review Figure 19.15**

genetic toolkit A set of developmental genes and proteins that is common to most animals and is hypothesized to be responsible for the evolution of their differing developmental pathways.

- The bodies of developing and mature organisms are organized into self-contained units, or modules, that can be modified independently. See **Animation 19.4**
- The genetic toolkit involves **genetic switches**—promoters, enhancers and repressors, signaling molecules, and signal transduction components—that can alter the expression of developmental genes in different modules independently of one another. **Review Figure 19.16**

genetic switches Mechanisms that control how the genetic toolkit is used, such as promoters and the transcription factors that bind them. The signal cascades that converge on and operate these switches determine when and where genes will be turned on and off.

- Developmental genes can be expressed in a modular fashion in different amounts (**heterometry**), at different times (**heterochrony**), or in different locations (**heterotopy**). **Review Figures 19.17- 19.19**

heterometry [Gk. different measure] Alteration in the level of gene expression, and thus in the amount of protein produced, during development, contributing to the evolution of different phenotypes in the adult. (Contrast with heterochrony, heterotopy.)

heterochrony [Gk. different time] Alteration in the timing of developmental events, contributing to the evolution of different phenotypes in the adult. (Contrast with heterometry, heterotopy.)

heterotopy [Gk. different place] Spatial differences in gene expression during development, controlled by developmental regulatory genes and contributing to the evolution of distinctive adult phenotypes.

► 19.5 Developmental Gene Changes Can Shape Evolution

- Morphological differences among species can result from mutations in the genes that regulate the development of modules such as body segments or wings. **Review Figure 19.20**
- Because many genes that govern development have been highly conserved, similar traits are likely to evolve repeatedly, especially among closely related species. This process is called **parallel evolution**. **Review Figure 19.21**

parallel evolution The repeated evolution of similar traits, especially among closely related species; facilitated by conserved developmental genes.

Review

9.3 Alterations of Hox genes can result in homeotic mutations.

9.4 Heterochrony has significant importance, as illustrated by the extreme length of a giraffe's neck.

9.4 Spatial differences in the expression of a developmental gene are known as heterotopy.

9.5 A major developmental change can be caused by an alteration in a regulatory molecule.

Differences in bristle patterns in flies often have implications for how the flies sense the world—and can even affect their courtship behavior. Bristles can be important in the evolution of these flies.

Two hypothetical, closely related fly species differ primarily in the length of bristles on the third segment of the thorax. The transcription factor Hairball is thought to be involved in determining the differences between these structures. The figure below shows the gene expression pattern for both species over the course of time.

Questions

1. Describe the results and formulate a hypothesis for the role of the transcription factor in the two species. Assess whether this is an example of heterotopy, heterometry, or heterochrony.
2. Outline an experimental approach that would test the hypothesis generated in Question 1, and provide the expected results.
3. Bristles ordinarily do not grow on the other two thoracic segments of either of these species, and *hairball* is not expressed at high levels in these segments. A third species, Species 3, has hairs on the other thoracic segments and expresses *hairball* during development in these segments. Predict what would happen if *hairball* were expressed in the other thoracic segments in Species 1 and 2. Assess whether this is an example of heterotopy, heterometry, or heterochrony.

1. Suppose a *Hox* gene regulates *hairball* expression, and Species 3 had a variant of the gene that differed by one nucleotide from the variant in Species 1 and 2. How would you test whether this *Hox* gene was responsible for the differences between Species 3 and Species 1 and 2?

An Evolutionary Arms Race Between Bats and Moths

Many species of bats roost by day and fly out as night approaches. The mass exodus of thousands or even millions of bats from a roost is an impressive sight, often attracting crowds of human bat-watchers. In urban areas, the cavities under bridges can attract enormous colonies of bats. People once feared these urban bat colonies, but we now know that many species of bats prey on night-flying insects, including mosquitoes and agricultural pests. Each bat can consume a third of its weight in insects per night, so just 1,000 bats consume about 4 tons of insects every year.

Most bats catch insects in flight at night. About 50 million years ago, bats evolved the ability to echolocate, which allows them to detect flying insects (such as moths) in darkness. The bats produce ultrasonic sounds, and compare these outgoing sound pulses with the returning echoes of the pulses that bounce off the flying moths. Because bats are among the greatest threats to night-flying insects, any insect that can escape detection by bats is much more likely to survive and reproduce. Inherited traits that lead to greater survival increase in the population over time as surviving moths pass these traits on to their offspring.

Many groups of night-flying insects, including several groups of moths, have evolved the ability to detect the ultrasonic sounds of bats. When such a moth hears a bat, it flies away from the source of the sound. If the bat is too close, the moth may dive rapidly to avoid capture. The moths in each generation that are better able to detect and avoid bats leave more offspring, so moths gradually evolve more effective escape mechanisms.

As moths get better at avoiding bats, why don't the bats starve? Because populations of bats are evolving too. In each generation, the individual bats best able to detect and capture flying insects get the most food, which allows them to put the most effort into

reproduction. Their offspring inherit their prey-detection capabilities, so populations of bats evolve more efficient insect-catching abilities, even as the moth populations evolve better escape strategies. This gradual change in both moth and bat populations is known as evolution by natural selection—a process that is constantly shaping and changing all species of life on our planet.

QA How do complex traits like echolocation, or the ability to avoid detection by echolocation, evolve in the first place?

20.1 Evolution Is Both Factual and the Basis of Broader Theory

All biological populations change in their genetic makeup over time. Change in the genetic composition of populations over time is called [evolution](#). We can, and do, observe evolutionary change on a regular basis, both in laboratory experiments and in natural populations. We measure the rate at which new mutations arise, observe the spread of new genetic variants through a population, and see the effects of genetic change on the form and function of organisms. In the fossil record, we observe the long-term morphological changes (which are the result of underlying genetic changes) that have occurred among living organisms. These underlying changes in the genetic makeup of populations drive the origin and extinction of species and fuel the diversification of life.

evolution Any gradual change. Most often refers to organic or Darwinian evolution, which is the genetic and resulting phenotypic change in populations of organisms from generation to generation. (See macroevolution, microevolution. Contrast with speciation.)

focus your learning

Evolution is directly observable and is a universal principle of life.

A scientific theory is a well-supported, evidence-based explanation of natural phenomena.

Natural selection favors traits that convey survival and reproductive advantages.

Evolution is responsible for the vast diversity of life on Earth.

In addition to observing and recording physical changes over evolutionary time, biologists have accumulated a large body of evidence about *how* these changes occur, and about *what* evolutionary changes have occurred in the past. The resulting understanding of the processes of evolutionary change is known as [evolutionary theory](#).

evolutionary theory The understanding and application of the mechanisms of evolutionary change to biological problems.

Evolutionary theory has many useful applications. We constantly apply it to the study and treatment of diseases. Evolutionary theory is critical to the development of better agricultural crops and practices, and to the development of industrial processes that produce new molecules with useful properties. At a more basic level, knowledge of evolutionary theory allows biologists to understand how life diversified. It also helps us make predictions about the biological world.

In everyday speech, people tend to use the word “theory” to mean an untested hypothesis, or even a guess. But evolutionary theory does not refer to any single hypothesis, and it certainly is not guesswork. A vast and rich array of geological, morphological, behavioral, and molecular data all support the factual basis of evolution. Observations of fossils and natural populations are supported by experiments that demonstrate the basic operation of evolutionary processes.

When we refer to evolutionary theory, we are referring to our understanding of the processes

that result in genetic changes in populations over time. We then apply that understanding to interpret the changes we observe in natural populations. We can directly observe the evolution of many living organisms. We can observe the yearly changes in the viruses that give us the flu, but it is evolutionary theory that allows us to apply our observations to the task of developing more effective vaccines against these viruses. Several processes of evolutionary change are recognized, and the scientific community is continually using evolutionary theory to expand its understanding of how and when these processes apply to particular biological problems.

Media Clip 20.1 **Watching Evolution in Real Time** www.Life11e.com/mc20.1

Darwin and Wallace introduced the idea of evolution by natural selection

In the early 1800s, it was not yet evident to many people that populations of living organisms evolve. But several biologists had suggested that the species living on Earth had changed over time—that is, that evolution had taken place. Jean-Baptiste Lamarck, for one, presented strong evidence for the fact of evolution in 1809, but his ideas about *how* it occurred were not convincing. At that time, no one had yet envisioned a viable process for evolution.

In the 1820s, a young Charles Darwin became passionately interested in the subjects of geology (with its new sense of Earth's great age) and natural history (the scientific study of how different organisms function and carry out their lives in nature). Despite these interests, he planned, at his father's behest, to become a doctor. But surgery conducted without anesthesia nauseated Darwin, and he gave up medicine to study at Cambridge University for a career as a clergyman in the Church of England. Always more interested in science than in theology, he gravitated toward scientists on the faculty, especially the botanist John Henslow. In 1831, Henslow recommended Darwin for a position on HMS *Beagle*, a Royal Navy vessel that was preparing for a survey voyage around the world ([Figure 20.1](#)).

Charles Robert Darwin

Figure 20.1 Darwin and the Voyage of the Beagle The mission of HMS *Beagle* was to chart the oceans and collect oceanographic and biological information from around the world. The world map indicates the ship's path; the inset map shows the Galápagos Islands, whose organisms were an important source of Darwin's ideas on natural selection. The portrait is of Charles Darwin at age 27, shortly after the *Beagle* returned to England.

Whenever possible during the five-year voyage, Darwin went ashore to study rocks and to observe and collect plants and animals. He noticed striking differences between the species he saw in South America and those of Europe. He observed that the species of the temperate regions of South America (Argentina and Chile) were more similar to those of tropical South America (Brazil) than they were to temperate European species. When he explored the islands of the Galápagos archipelago, west of Ecuador, he noted that most of the animals were endemic to the islands (meaning they were unique and found nowhere else), although they were similar to animals found on the mainland of South America. Darwin also observed that the fauna of the Galápagos differed from island to island. He postulated that some animals had come to the archipelago from mainland South America and had subsequently undergone different changes on each of the islands. He wondered what might account for these changes.

When he returned to England in 1836, Darwin continued to ponder his observations. His thoughts were strongly influenced by the geologist Charles Lyell, who had recently popularized the idea that Earth had been shaped by slow-acting forces that are still at work today. Darwin reasoned that similar thinking could be applied to the living world. Within a decade, he had developed the framework of an explanatory theory for evolutionary change based on three major propositions:

- Species are not immutable; they change over time.
- Divergent species share a common ancestor and have diverged from one another gradually over time (a concept Darwin termed **descent with modification**).
- Changes in species over time can be explained by **natural selection**: the increased survival and reproduction of some individuals compared with others, based on differences in their traits.

descent with modification Darwin's premise that all species share a common ancestor and

have diverged from one another gradually over time.

natural selection The differential contribution of offspring to the next generation by various genetic types belonging to the same population. The mechanism of evolution proposed by Charles Darwin.

 Activity 20.1 **Darwin's Voyage** www.Life11e.com/ac20.1

The first of these propositions was not unique to Darwin; several earlier authors had argued for the fact of evolution. A more revolutionary idea was his second proposition, that divergent species are related to one another through common descent. But Darwin is probably best known for his third proposition, that of natural selection.

Darwin realized that many more individuals of most species are born than survive to reproduce. He also knew that, although offspring usually resemble their parents, offspring are not identical to one another or to either parent. Finally, he was well aware that human breeders of plants and animals often selected their breeding stock based on the occurrence of particular traits. Over time, this selection resulted in dramatic changes in the appearance of the descendants of those plants or animals. In natural populations, wouldn't the individuals with the best chances of survival and reproduction be similarly "selected," and thus pass their traits on to the next generation? Darwin's simple but powerful idea was that nature did the selecting in natural populations on the basis of traits that resulted in greater survival and, eventually, greater likelihood of reproduction.

In 1844, Darwin wrote a long essay describing the role of natural selection as a process of evolution. But he was reluctant to publish it, preferring to assemble more evidence first. Darwin's hand was forced in 1858, when he received a letter and manuscript from another traveling English naturalist, Alfred Russel Wallace, who was studying the plants and animals of the Malay Archipelago. Wallace asked Darwin to evaluate his manuscript, which included an explanation of natural selection almost identical to Darwin's. Darwin was at first dismayed, believing Wallace to have preempted his idea. Parts of Darwin's 1844 essay, together with Wallace's manuscript, were presented to the Linnaean Society of London on July 1, 1858, thereby crediting both men for the idea of natural selection. Darwin then worked quickly to finish his full-length book, *On the Origin of Species*, which was published the following year.

 Animation 20.1 **Natural Selection** www.Life11e.com/a20.1

Although Darwin and Wallace independently articulated the concept of natural selection, Darwin developed his ideas first. Furthermore, *On the Origin of Species* proved to be a stunning work of scholarship that provided exhaustive evidence from many fields supporting both the premise of evolution itself and the understanding of natural selection as a process of evolution. Thus both concepts are more closely associated with Darwin than with Wallace.

The publication of *On the Origin of Species* in 1859 stirred considerable interest (and controversy) among scientists and the public alike. Scientists spent much of the rest of the nineteenth century amassing biological and paleontological data to test evolutionary ideas and document the history of life on Earth. By 1900, the fact of biological evolution (defined at that time as change in the physical characteristics of populations over time) was established beyond any reasonable doubt. As biologists discovered the details of genetic inheritance in the twentieth century, the genetic mechanisms of evolution became clear. The development of methods for sequencing DNA in the late 1970s allowed biologists to document evolutionary changes within and between species with great precision. This technology led to explosive growth in the field of evolutionary biology. In the past three decades, well over a quarter of a million scientific papers on evolutionary observations, experiments, and theory have been published.

20.1 recap

Evolution, or changes in gene frequencies in biological populations over time, is directly observable. Natural selection occurs when specific alleles increase the rates of survival or reproduction of individuals in a population relative to individuals that do not possess those alleles. Under such conditions, the frequency of the favored allele increases in the population from one generation to the next.

learning outcomes

You should be able to:

- Describe an example in which evolution by natural selection can be observed directly within a human lifetime.
- Differentiate between the everyday use of the word “theory” and a scientific theory.
- Apply the principles of selection to predict and explain evolutionary outcomes.
- Explain how evolution produces diversity and provides evidence of common ancestry.

1. Why do biologists speak of “evolutionary theory” if the facts of evolution are not in doubt?
2. Antibiotics are drugs that kill most bacteria, but genetic mutations can allow some individual bacteria to survive short-term exposure to these drugs. How would you expect the frequency of resistant bacteria to change over time in populations of bacteria that were exposed to an antibiotic drug on a regular basis? Why do you think antibiotics come with a warning to take the full course of the treatment, rather than stopping after you begin to feel better?
3. In what ways does selection by humans in developing agricultural crops differ from natural selection? Can you give an example of a trait that might be favored by artificial selection in agriculture, but selected against by natural selection in a wild population?
4. Natural selection cannot adapt populations to conditions they have not experienced. Yet many organisms appear to respond to natural events before they happen. For example, many mammals go into hibernation while it is still quite warm. Similarly, many birds leave the temperate zone for their southern wintering grounds long before winter has arrived. How do you think such “anticipatory” behaviors evolve?
5. As more humans live longer, many people face degenerative conditions such as Alzheimer’s disease that (in most cases) are linked to advancing age. Assuming that some individuals may be genetically predisposed to successfully combat these conditions, is it likely that natural selection alone would act to favor such a predisposition in human populations? Why or why not?

Although the importance of natural selection to evolution has been confirmed in many thousands of scientific studies, it is not the only process that drives evolution. In the next section we’ll consider a more complete view of evolutionary processes and how they operate.

20.2 Mutation, Selection, Gene Flow, Genetic Drift, and Nonrandom Mating Result in Evolution

The word “evolution” is often used in a general sense to mean simply “change,” but in a biological context “evolution” refers specifically to change in the genetic makeup of populations over time. Developmental changes that occur in a single individual over the course of the life cycle are not the result of evolutionary change. Evolution is genetic change across generations of a **population**—a group of individuals of a single species that live and interbreed in a particular geographic area at the same time. It is important to remember that *individuals do not evolve; populations do*.

population (1) In biology, any group of organisms coexisting at the same time and in the same place and capable of interbreeding with one another. (2) In statistics, a study group of interest.

focus your learning

The terms “adapt,” “evolve,” and “population” have specific scientific meanings.

Evolution is the result of five major processes: mutation, natural selection, gene flow, genetic drift, and nonrandom mating.

The premise of natural selection was one of Darwin’s principal insights and has been demonstrated to be an important process of evolution, but natural selection does not act alone. Four additional processes—mutation, gene flow, genetic drift, and nonrandom mating— affect the genetic makeup of populations over time. Before we consider how the other processes can change the frequencies of gene variants in a population, we need to understand how mutation brings such variants into existence.

Mutation generates genetic variation

The origin of genetic variation is mutation. As described in [Key Concept 15.1](#), a mutation is any change in the nucleotide sequences of an organism’s DNA. The process of DNA replication is not perfect, and some changes appear almost every time a genome is replicated. Mutations occur randomly with respect to an organism’s needs; it is natural selection acting on this random variation that results in adaptation. Most mutations are either harmful to their bearers (deleterious mutations) or have no effect (neutral mutations). But a few mutations are beneficial, and even previously deleterious or neutral alleles may become advantageous if environmental conditions change. In addition, mutation can restore genetic variation that other evolutionary processes have removed. Thus mutation both creates and helps maintain genetic variation in populations.

Mutation rates can be high, especially in viruses and bacteria, which explains the rapid evolution of many pathogens. But in many protein-coding genes of multicellular organisms, the mutation rate is very low (on the order of 10^{-8} to 10^{-9} changes per base pair of DNA per generation). Even low overall mutation rates, however, create considerable genetic variation,

because each of a large number of genes may change, and populations often contain large numbers of individuals. For example, if the probability of a point mutation (an addition, deletion, or substitution of a single base) were 10^{-9} per base pair per generation, then each human gamete—the DNA of which contains 3×10^9 base pairs—would average three new point mutations ($3 \times 10^9 \times 10^{-9} = 3$), and each zygote would carry an average of six new mutations. The current human population of about 7 billion people would thus be expected to carry about 42 billion new mutations (i.e., changes in the nucleotide sequences of their DNA that were not present one generation earlier). So even though the mutation rate in humans is low, human populations still contain enormous genetic variation on which other evolutionary processes can act.

As a result of mutation, different forms of a gene, known as **alleles**, may exist at a particular chromosomal locus (see [Key Concept 12.1](#)). At any particular locus, a single diploid individual has no more than two of the alleles found in the population to which it belongs. The sum of all copies of all alleles at all loci found in a population constitutes that population's **gene pool** ([Figure 20.2](#)). (We can also refer to the gene pool for a particular chromosomal locus or loci.) The gene pool is the sum of the genetic variation in the population. The proportion of each allele in the gene pool is the ***allele frequency**. Likewise, the proportion of each genotype among individuals in the population is the genotype frequency.

allele (a leel') [Gk. *allos*: other] The alternate form of a genetic character found at a given locus on a chromosome.

gene pool All of the different alleles of all of the genes existing in all individuals of a population.

Figure 20.2 A Gene Pool A gene pool is the sum of all the alleles found in a population or at a particular locus in that population. This figure shows the gene pool for one locus, X, in a population of diploid organisms. The allele frequencies in this case are 0.20 for X_1 , 0.50 for X_2 , and 0.30 for X_3 (see [Figure 20.10](#)).

A simple experiment demonstrates how mutations accumulate in populations in a continuous, almost constant fashion over time ([Figure 20.3](#)). Lines of the bacterium *E. coli* were grown in the laboratory for 20,000 generations, and the genomes were sequenced from individuals in the experimental lines at least once every 5,000 generations. Over the experiment, the lines accumulated about 45 changes to their genomes, and these changes appeared at a fairly constant rate over time. All living organisms experience a similar accumulation of mutations over time (although the rate of change differs among species), and these changes provide the raw material for evolution.

Figure 20.3 Mutations Accumulate Continuously An experimental lineage of the bacterium *Escherichia coli* was propagated in the laboratory for 20,000 generations. Genomes were sequenced from individuals sampled at various points during the experiment and were compared with the genome of the ancestral clone. Note that mutations accumulated at a relatively constant rate throughout the experiment.

Selection acting on genetic variation leads to new phenotypes

As a result of mutation, the gene pools of nearly all populations contain variation for many traits. Selection that favors different traits can lead to distinctly different lineages that descend from the same ancestor. For example, artificial selection for different traits in a single European species of wild mustard produced many important crop plants ([Figure 20.4](#)). Agriculturalists were able to achieve these results because the original mustard population had genetic variation for the characters of interest (such as stem thickness or number of leaves).

Figure 20.4 Many Vegetables from One Species All the crop plants shown here derive from a single wild mustard species. European agriculturalists produced these crop species by selecting and breeding plants with unusually large buds, stems, leaves, or flowers. The results substantiate the vast amount of variation present in the gene pool of the ancestral species.

Darwin compared artificial selection, which was commonly practiced by animal and plant breeders, with natural selection that occurred in natural populations. Many of Darwin's observations on the nature of variation and selection came from domesticated plants and animals. Darwin bred pigeons and thus knew firsthand the astonishing diversity in color, size, form, and behavior that breeders could achieve ([Figure 20.5](#)). He recognized close parallels between selection by breeders and selection in nature. Whereas artificial selection resulted in traits that were preferred by the human breeders, natural selection resulted in traits that helped organisms survive and reproduce more effectively. In both cases, selection simply increased the frequency of the favored trait from one generation to the next.

Figure 20.5 Artificial Selection Charles Darwin, who raised pigeons as a hobby, noted similar forces at work in artificial and natural selection. The “fancy” pigeons shown here represent 3 of the more than 300 varieties derived from the wild rock pigeon (*Columba livia*; left) by artificial selection on characters such as color and feather distribution.

Laboratory experiments also demonstrate the existence of considerable genetic variation in populations, and show how this variation can lead to evolution through selection. In one such

experiment, investigators bred populations of the fruit fly *Drosophila melanogaster* with high or low numbers of bristles on their abdomens from an initial population with intermediate numbers of bristles. After 35 generations, all flies in both the high- and low-bristle lineages had bristle numbers that fell well outside the range found in the original population ([Figure 20.6](#)). Selection for high and low bristle numbers resulted in new combinations of the many different genes that were present in the original population, so that the phenotypic variation seen in subsequent generations fell outside the phenotypic variation seen in the original population.

Figure 20.6 Artificial Selection Reveals Genetic Variation When investigators subjected *Drosophila melanogaster* to artificial selection for abdominal bristle number, that character evolved rapidly. The graph shows the number of flies with different numbers of bristles in the original population and after 35 generations of artificial selection for low and for high bristle numbers.

Q: How did flies in the selected populations end up with fewer or more bristles than were observed in any of the flies in the original population?

Natural selection increases the frequency of beneficial mutations in populations

Darwin knew that far more individuals of most species are born than survive to reproduce. He also knew that, although offspring tend to resemble their parents, the offspring of most organisms are not identical either to their parents or to one another. He suggested that slight differences among individuals affect the chance that a given individual will survive and reproduce, which increases the frequency of the favored trait in the next generation. A favored trait that spreads through a population by natural selection is known as an [adaptation](#); this word is used to describe both the trait itself and the process that produces the trait.

adaptation (a dap tay' shun) (1) In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the

evolutionary process that leads to the development or persistence of such a trait. (2) In sensory neurophysiology, a sensory cell's loss of sensitivity as a result of repeated stimulation.

▶ investigatinglife Do Long Wing Tails Help Moths Escape Bat Predation?

experiment

Original Paper: Barber, J. R., B. C. Leavell, A. L. Keener, J. W. Breinholt, B. A. Chadwell, C. J. W. McClure, G. M. Hill and A. Y. Kawahara. 2015. Moth tails divert bat attack: Evolution of acoustic deflection. *Proceedings of the National Academy of Sciences USA* 112: 2812–2816.

Many groups of moths have evolved the ability to hear the ultrasounds that bats produce for echolocation. These moths can then use evasive behavior to avoid predation by the bats. But almost half of all moths lack ears to hear the sounds produced by bats. Jesse Barber and his colleagues noticed that many non-hearing moths have long, posterior wing extensions ("wing tails"), and wondered if these wing tails might serve to deflect attacks by echolocating bats.

HYPOTHESIS ▶ As the long tails on moth wings flutter in flight, they serve to deflect the attacks of echolocating bats.

METHOD

1. Remove the wing tails from an experimental group of luna moths (*Actias luna*).
2. In an experimental setting, compare the capture rate by big brown bats (*Eptesicus fuscus*) of moths with and without wing tails.
3. Control for the effects of wing tail size by conducting comparable experiments on moths with various wing tail sizes, in species that naturally lack wing tails.
4. Compare the flying efficiency of luna moths with and without wing tails, to test the possibility that wing tails improve flying performance.

RESULTS

The successful capture rate by bats on luna moths was much higher in moths that had their wing tails removed. Large wing tail size does

seem to have an effect on reducing successful predation as well, but the long wing tails of luna moths provide a much greater benefit to predation avoidance than predicted by the increase in wing tail size alone. The removal of wing tails from luna moths had no significant effect on the flight performance of the moths. The graph shows successful capture rate by bats on luna moths, with and without wing tails. Brackets show 95% confidence intervals.

CONCLUSION ▶ The tail extensions on the wings of luna moths reduce the rate of successful bat attacks on the moths. Bats attack the fluttering wing tails of luna moths rather than their bodies, allowing the moths to escape. The wing tails do not provide improvements in flight performance, but rather in predation avoidance.

Biologists regard an organism as being adapted to a particular environment when they can demonstrate that a slightly different organism reproduces and survives less well in that environment. To understand adaptation, biologists compare the performances of individuals that differ in their traits.

In the story that opens this chapter, we learned that many groups of moths have evolved the ability to detect ultrasounds of bats, which allows the moths to fly away from the bats or use evasive flight behavior to avoid predation. But many species of moths are unable to hear bats, so they would seem to be at a huge disadvantage. As described in **Investigating Life: Do Long Wing Tails Help Moths Escape Bat Predation?**, Jesse Barber and his colleagues noticed that several groups of non-hearing moths have long extensions of their wings (“wing tails”), and they wondered if these structures might serve to distract echolocating bats and allow the moths to escape. The researchers cut the wing tails off some individual moths and compared the rates of bat predation, and flight performance, in the moths with and without wing tails. They found that the wing tails had very little effect on the moth’s flying efficiency, but conveyed a huge advantage in reducing bat predation. The wing tails flutter as the moths fly, and the echolocation system of the bats is more likely to locate the fluttering nonessential wing tail than the body of the moth, thereby allowing a moth to survive a bat attack. Thus, the wing tails appear to be an adaptation that helps moths avoid bat predation.

Gene flow may change allele frequencies

Few populations are completely isolated from other populations of the same species. Migration of individuals and movements of gametes (in pollen, for example) between populations—a phenomenon called ***gene flow**—can change allele frequencies in a population. If the arriving individuals survive and reproduce in their new location, they may add new alleles to the population's gene pool, or they may change the frequencies of alleles present in the original population.

Genetic drift may cause large changes in small populations

In small populations, **genetic drift**—random changes in allele frequencies from one generation to the next—may produce large changes in allele frequencies over time. Harmful alleles may increase in frequency, and rare advantageous alleles may be lost. Even in large populations, genetic drift can influence the frequencies of neutral alleles (which do not affect the survival and reproductive rates of their bearers).

genetic drift Changes in gene frequencies from generation to generation as a result of random (chance) processes.

 Activity 20.3 Genetic Drift Simulation www.Life11e.com/ac20.3

To illustrate the effects of genetic drift, suppose there are only two females in a small population of normally brown mice, and one of these females carries a newly arisen dominant allele that produces black fur. Even in the absence of any selection, it is unlikely that the two females will produce exactly the same number of offspring. Even if they do produce identical litter sizes and identical numbers of litters, chance events that have nothing to do with genetic characteristics are likely to result in differential mortality among their offspring. If each female produces one litter, but a flood envelops the black female's nest and kills all of her offspring, the novel allele could be lost from the population in just one generation. In contrast, if the brown female's litter is lost, then the frequency of the newly arisen allele (and phenotype) for black fur will rise dramatically in just one generation.

Genetic drift is especially potent when a population is reduced dramatically in size. Even populations that are normally large may occasionally pass through environmental events that only a small number of individuals survive, a situation known as a **population bottleneck**. The effect of genetic drift in such a situation is illustrated in **Figure 20.7**, in which red and yellow beans represent two alleles of a gene. Most of the beans in the small sample of the “population” that “survives” the bottleneck event are, just by chance, red, so the new population has a much higher frequency of red beans than the previous generation had. In a real population, the red and yellow allele frequencies would be described as having “drifted.”

population bottleneck A period during which only a few individuals of a normally large population survive.

Figure 20.7 A Population Bottleneck Population bottlenecks occur when only a few individuals survive a random event. The result may be a change in allele frequencies within the population.

A population forced through a bottleneck is likely to lose much of its genetic variation. For example, when Europeans first arrived in North America, millions of greater prairie-chickens (*Tympanuchus cupido*) inhabited the midwestern prairies. As a result of hunting and habitat destruction by the new settlers, the Illinois population of this species plummeted from about 100 million birds in 1900 to fewer than 50 individuals in the 1990s. A comparison of DNA from birds collected in Illinois during the middle of the twentieth century with DNA from the surviving population in the 1990s showed that Illinois prairie-chickens have lost most of their genetic diversity. Loss of genetic variation in small populations is one of the problems facing biologists who attempt to protect endangered species.

Genetic drift can have similar effects when a few pioneering individuals colonize a new region. Because of its small size, the colonizing population is unlikely to possess all of the alleles found in the gene pool of its source population. The resulting change in genetic variation, called a **founder effect**, is equivalent to that in a large population reduced by a bottleneck.

founder effect Random changes in allele frequencies resulting from establishment of a population by a very small number of individuals.

Nonrandom mating can change genotype or allele frequencies

Mating patterns often alter genotype frequencies because the individuals in a population do not choose mates at random. For example, self-fertilization is common in many groups of organisms, especially plants. Any time individuals mate preferentially with other individuals of the same genotype (including themselves), homozygous genotypes will increase in frequency and heterozygous genotypes will decrease in frequency over time. The opposite effect (more

heterozygotes, fewer homozygotes) is expected when individuals mate primarily or exclusively with individuals of different genotypes.

Many nonrandom mating systems produce changes in genotype frequencies but not in allele frequencies, and thus do not, by themselves, result in evolutionary change in a population. However, nonrandom mating systems that result in different reproductive success among individuals do produce allele frequency changes from one generation to the next. One such process, [sexual selection](#) occurs when individuals of one sex mate preferentially with particular individuals of the opposite sex rather than at random.

sexual selection Selection by one sex of characteristics in individuals of the opposite sex. Also, the favoring of characteristics in one sex as a result of competition among individuals of that sex for mates.

Sexual selection was first suggested by Charles Darwin, who developed the idea to explain the evolution of conspicuous traits that would appear to inhibit survival, such as bright colors and elaborate courtship displays in males of many species. He hypothesized that these features either improved the ability of their bearers to compete for access to mates (intrasexual selection) or made their bearers more attractive to members of the opposite sex (intersexual selection).

Darwin argued that while natural selection typically favors traits that enhance the survival of their bearers or their bearers' descendants, sexual selection is primarily about successful reproduction. An animal that survives but fails to reproduce makes no contribution to the next generation. Thus sexual selection may favor traits that enhance an individual's chances of reproduction even when these traits reduce its chances of survival. For example, females may be more likely to see or hear males with a given trait (and thus be more likely to mate with those males), even though the favored trait also increases the chances that the male will be seen or heard by a predator.

One example of a trait that Darwin attributed to sexual selection is the remarkable tail of the male African long-tailed widowbird (*Euplectes progne*), which is longer than the bird's head and body combined ([Figure 20.8](#)). Male widowbirds normally select, and defend from other males, a territory where they perform courtship displays to attract females. To investigate whether sexual selection drove the evolution of widowbird tails, a biologist clipped the tails of some captured male widowbirds and lengthened the tails of others by gluing on additional feathers. He then cut and reglued the tail feathers of still other males, which served as controls. Both short- and long-tailed males successfully defended their display territories, indicating that a long tail does not confer an advantage in male-male competition. However, males with artificially elongated tails attracted about four times more females than did males with shortened tails ([Figure 20.9](#)). Thus males with long tails pass on their genes to more offspring than do males with short tails, which leads to the evolution of this unusual trait.

Figure 20.8 What Is the Advantage? The extensive tail of the male African long-tailed widowbird inhibits its ability to fly. Darwin attributed the evolution of this seemingly nonadaptive trait to sexual selection.

experiment

Figure 20.9 Sexual Selection in Action

Original Paper: Andersson, M. 1982. Female choice selects for extreme tail length in a widowbird. *Nature* 299: 818–820.

Behavioral ecologist Malte Andersson tested Darwin's hypothesis that excessively long tails evolved in male widowbirds because female preference for longer-tailed males increased their mating and reproductive success.

HYPOTHESIS ▶ Female widowbirds prefer to mate with the male that displays the longest tail; longer-tailed males thus are favored by sexual selection because they will father more offspring.

METHOD

1. Capture males and artificially lengthen or shorten tails by cutting or gluing on feathers. In a control group, cut and replace tails to their normal length (to control for the effects of tail-cutting).
2. Release the males to establish their territories and mate.
3. Count the nests with eggs or young on each male's territory.

RESULTS

Male widowbirds with artificially shortened tails established and defended display sites successfully but fathered fewer offspring than did control or unmanipulated males. Males with artificially lengthened tails fathered the most offspring.

CONCLUSION ▶ Sexual selection in widowbirds has favored the evolution of long tails in the males.

20.2 recap

Evolutionary processes change the genetic structure of a population from one generation to the next. These processes include mutation, natural selection, gene flow, genetic drift, and nonrandom mating.

learning outcomes

You should be able to:

- Distinguish between the everyday and scientific uses of the terms “adapt” and “evolve.”
- Describe how each of the five processes of evolution can result in changes in gene frequencies across generations of a population.
- Predict the effects of each of the five processes of evolution on a population.

1. How is mutation a necessary component of the evolutionary processes?
2. What kind of traits would be more likely to evolve by genetic drift than by natural selection?
3. Describe conditions where nonrandom mating does and does not lead to evolution.
4. Can you think of reasons why gene flow might slow the evolution of a population?

The processes of mutation, natural selection, gene flow, genetic drift, and nonrandom mating can all result in evolutionary change. We will consider next how evolutionary change that results from these processes is measured.

***connect the concepts** As discussed in [Key Concept 12.1](#), alleles of different genes assort independently in meiosis. The frequencies with which different allele combinations will be expressed in offspring can be calculated using a Punnett square or probability theory.

***connect the concepts** If gene flow between two populations stops, those populations may diverge and become different species; see [Key Concept 22.2](#).

20.3 Evolution Can Be Measured by Changes in Allele Frequencies

Much of evolution occurs through gradual changes in the relative frequencies of different alleles in a population from one generation to the next. Major genetic changes can also be sudden, as happens when two formerly separated populations merge and hybridize, or when genes within a population are duplicated within the genome. But in most cases, we measure evolution by looking at changes in allele and genotype frequencies in populations over time.

focus your learning

Biologists detect and measure evolutionary changes in populations by calculating changes in allele frequencies over time.

The evolutionary processes acting on a population can be identified using Hardy-Weinberg equilibrium as a basis for calculations.

To measure allele frequencies in a population precisely, we would need to count every allele at every locus in every individual in the population. Fortunately, we do not need to make such complete measurements because we can reliably estimate allele frequencies for a given locus by counting alleles in a sample of individuals from the population. The sum of all allele frequencies at a locus is equal to 1, so measures of allele frequency range from 0 to 1.

An allele's frequency is calculated using the following formula:

$$p = \frac{\text{number of copies of the allele in the population}}{\text{total number of copies of all alleles in the population}}$$

If only two alleles (we'll call them *A* and *a*) for a given locus are found among the members of a diploid population, those alleles can combine to form three different genotypes: *AA*, *Aa*, and *aa*. A population with more than one allele at a locus is said to be polymorphic ("many forms") at that locus. Applying the formula above, as shown in [Figure 20.10](#), we can calculate the relative frequencies of alleles *A* and *a* in a population of *N* individuals as follows:

Let N_{AA} be the number that are homozygous for the *A* allele (*AA*).

Let N_{Aa} be the number that are heterozygous (*Aa*).

Let N_{aa} be the number that are homozygous for the *a* allele (*aa*).

1 In any population, where N is the total number of individuals in the population:

$$\text{Frequency of allele A} = p = \frac{2N_{AA} + N_{Aa}}{2N} \quad \text{Frequency of allele a} = q = \frac{2N_{aa} + N_{Aa}}{2N}$$

$$\begin{aligned} \text{Frequency of genotype AA} &= N_{AA}/N \\ \text{Frequency of genotype Aa} &= N_{Aa}/N \\ \text{Frequency of genotype aa} &= N_{aa}/N \end{aligned}$$

2 Compute the allele and genotype frequencies for two separate populations of $N = 200$:

Population 1 (mostly homozygotes)	Population 2 (mostly heterozygotes)
$N_{AA} = 90$, $N_{Aa} = 40$, and $N_{aa} = 70$	$N_{AA} = 45$, $N_{Aa} = 130$, and $N_{aa} = 25$
$p = \frac{180 + 40}{400} = 0.55$	$p = \frac{90 + 130}{400} = 0.55$
$q = \frac{140 + 40}{400} = 0.45$	$q = \frac{50 + 130}{400} = 0.45$
Freq. AA = $90/200 = 0.45$	Freq. AA = $45/200 = 0.225$
Freq. Aa = $40/200 = 0.20$	Freq. Aa = $130/200 = 0.65$
Freq. aa = $70/200 = 0.35$	Freq. aa = $25/200 = 0.125$

Figure 20.10 Calculating Allele and Genotype Frequencies Allele and genotype frequencies for a gene locus with two alleles in the population can be calculated using the equations in panel 1. When the equations are applied to two populations (panel 2), we find that the *frequencies of alleles A and a in the two populations* are the same, but the alleles are distributed differently between heterozygous and homozygous genotypes.

Note that $N_{AA} + N_{Aa} + N_{aa} = N$, the total number of individuals in the population, and that the total number of copies of both alleles present in the population is $2N$, because each individual is diploid. Each AA individual has two copies of the A allele, and each Aa individual has one copy of the A allele. Therefore the total number of A alleles in the population is $2N_{AA} + N_{Aa}$. Similarly, the total number of a alleles in the population is $2N_{aa} + N_{Aa}$. If p represents the frequency of A, and q represents the frequency of a, then

$$q = \frac{2N_{aa} + N_{Aa}}{2N}$$

and

$$p = \frac{2N_{AA} + N_{Aa}}{2N}$$

The calculations in [Figure 20.10](#) demonstrate two important points. First, notice that for each population, $p + q = 1$, which means that $q = 1 - p$. So when there are only two alleles at a given locus in a population, we can calculate the frequency of one allele and obtain the second allele's frequency by subtraction. If there is only one allele at a given locus in a population, its frequency is 1: the population is then monomorphic at that locus, and the allele is said to be [fixed](#).

fixed In population genetics, the change in a gene pool where there are at least two alleles of a gene to a situation where only one allele remains.

Second, notice that population 1 (consisting mostly of homozygotes) and population 2 (consisting mostly of heterozygotes) have the same allele frequencies for A and a. Thus they have the same gene pool for this locus. Because the alleles in the gene pool are distributed differently among individuals, however, the genotype frequencies of the two populations differ.

The frequencies of the different alleles at each locus and the frequencies of the different genotypes in a population describe that population's **genetic structure**. Allele frequencies measure the amount of genetic variation in a population, whereas genotype frequencies show how a population's genetic variation is distributed among its members. Other measures, such as the proportion of loci that are polymorphic, are also used to measure variation in populations. With these measurements, it becomes possible to consider how the genetic structure of a population changes or remains the same over generations—that is, to measure evolutionary change.

genetic structure The frequencies of different alleles at each locus and the frequencies of different genotypes in a Mendelian population.

Evolution will occur unless certain restrictive conditions exist

In 1908, the British mathematician Godfrey Hardy and the German physician Wilhelm Weinberg independently deduced the conditions that must prevail if the genetic structure of a population is to remain the same over time. If the conditions they identified do not exist, then evolution will occur. The resulting principle is known as **Hardy–Weinberg equilibrium**. Hardy–Weinberg equilibrium describes a model in which allele frequencies do not change across generations and genotype frequencies can be predicted from allele frequencies (**Figure 20.11**). The principles of Hardy–Weinberg equilibrium apply only to sexually reproducing organisms. Several conditions must be met for a population to be at Hardy–Weinberg equilibrium. Note that the following conditions correspond inversely to the five principal processes of evolution (discussed in [Key Concept 20.2](#)):

Hardy–Weinberg equilibrium In a sexually reproducing population, the allele frequency at a given locus that is not being acted on by agents of evolution; the conditions that would result in no evolution in a population.

Generation I (Founder population)

Generation II (Hardy–Weinberg equilibrium restored)

Figure 20.11 One Generation of Random Mating Restores Hardy–Weinberg Equilibrium Generation I of this population is made up of migrants from several source populations and so is not initially in Hardy–Weinberg equilibrium. After one generation of random mating, the allele frequencies are unchanged, and the genotype frequencies return to Hardy–Weinberg expectations. The lengths of the sides of each rectangle are proportional to the allele frequencies in the population; the areas of the rectangles are proportional to the genotype frequencies.

There is no mutation. The alleles present in the population do not change, and no new alleles

are added to the gene pool.

There is no selection among genotypes. Individuals with different genotypes have equal probabilities of survival and equal rates of reproduction.

There is no gene flow. There is no movement of individuals into or out of the population or reproductive contact with other populations.

Population size is infinite. The larger a population, the smaller will be the effect of genetic drift.

Mating is random. Individuals do not preferentially choose mates with certain genotypes.

If these idealized conditions hold, two major consequences follow. First, the frequencies of alleles at a locus remain constant from generation to generation. Second, following one generation of random mating, the genotype frequencies occur in the following proportions:

Genotype	AA	Aa	aa
Frequency	p^2	$2pq$	q^2

To understand why these consequences are important, start by considering a population that is *not* in Hardy–Weinberg equilibrium, such as generation I in [Figure 20.11](#). This could occur, for example, if the initial population is founded by migrants from several other populations, thus violating the Hardy–Weinberg assumption of no gene flow. In this example, generation I has more homozygous individuals and fewer heterozygous individuals than would be expected under Hardy–Weinberg equilibrium (a condition known as heterozygote deficiency).

Even with a starting population that is not in Hardy–Weinberg equilibrium, we can predict that after a single generation of random mating, and if the other Hardy–Weinberg assumptions are not violated, the allele frequencies will remain unchanged, but the genotype frequencies will return to Hardy–Weinberg expectations. Let's explore why this is true.

In generation I of [Figure 20.11](#), the frequency of the A allele (p) is 0.55. Because we assume that individuals select mates at random, without regard to their genotype, gametes carrying A or a combine at random—that is, as predicted by the allele frequencies p and q . Thus in this example, the probability that a particular sperm or egg will bear an A allele is 0.55. In other words, 55 out of 100 randomly sampled sperm or eggs will bear an A allele. Because $q = 1 - p$, the probability that a sperm or egg will bear an a allele is $1 - 0.55 = 0.45$.

To obtain the probability of two A-bearing gametes coming together at fertilization, we multiply the two independent probabilities of their occurrence:

$$p \times p = p^2 = (0.55)^2 = 0.3025$$

Therefore 0.3025, or 30.25 percent, of the offspring in generation II will have homozygous genotype AA. Similarly, the probability of two a-bearing gametes coming together is

$$q \times q = q^2 = (0.45)^2 = 0.2025$$

which means that 20.25 percent of generation II will have the aa genotype.

There are two ways of producing a heterozygote: an A sperm may combine with an a egg, the probability of which is $p \times q$; or an a sperm may combine with an A egg, the probability of which is $q \times p$. Consequently, the overall probability of obtaining a heterozygote is $2pq$, or 0.495. The frequencies of the AA, Aa, and aa genotypes in generation II of [Figure 20.11](#) now meet Hardy–Weinberg expectations, and the frequencies of the two alleles (p and q) have not changed from generation I.

Under the assumptions of Hardy–Weinberg equilibrium, allele frequencies p and q remain

constant from generation to generation. If Hardy–Weinberg assumptions are violated and the genotype frequencies in the parental generation are altered (say, by the loss of a large number of AA individuals from the population), then the allele frequencies in the next generation will be altered. However, based on the new allele frequencies, another generation of random mating will be sufficient to restore the genotype frequencies to Hardy–Weinberg equilibrium.

Activity 20.4 Hardy–Weinberg Equilibrium www.Life11e.com/ac20.4

Deviations from Hardy–Weinberg equilibrium show that evolution is occurring

You probably have realized that populations in nature never meet the stringent conditions necessary to be at Hardy–Weinberg equilibrium—which explains why all biological populations evolve. Why, then, is this model considered so important for the study of evolution? There are two reasons. First, the equation is useful for predicting the approximate genotype frequencies of a population from its allele frequencies. Second—and crucially—the model allows biologists to evaluate which processes are acting on the evolution of a particular population. The specific patterns of deviation from Hardy–Weinberg equilibrium can help us identify the various processes of evolutionary change.

20.3 recap

Hardy–Weinberg equilibrium describes the theoretical conditions required for evolution *not* to occur. Deviations from Hardy–Weinberg expectations provide information about how evolution *is* occurring in a given population.

learning outcomes

You should be able to:

- Calculate the allele frequencies for two alleles at a given locus in a diploid population.
- Calculate observed and expected genotype frequencies from allele frequencies based on the principles of Hardy–Weinberg equilibrium.
- Analyze data and formulate hypotheses to explain deviations from Hardy–Weinberg expectations in observed genotype frequencies.

1. The following sample lists the genotype at locus A for 10 individuals in a diploid population: AA, AA, Aa, Aa, Aa, Aa, aa, aa, aa, aa.
 - a. Based on this sample, what is the observed frequency of allele a? The observed frequency of allele A?
 - b. What are the observed frequencies of genotypes aa, Aa, and AA?
 - c. After one generation of random mating, what would be the Hardy–Weinberg expectations for the frequencies of genotypes aa, Aa, and AA?
2. In a population of toads, allele A is present at a frequency of 0.2, and allele a is present at a frequency of 0.8. Based on Hardy–Weinberg expectations, what is the expected frequency of the genotype Aa in the population?
3. Assume that the observed frequency of the genotype Aa in the toad population in Question 2 is 0.15, rather than the expected frequency you calculated. What are some possible explanations?

Our discussion so far has focused on changes in allele frequencies at a single gene locus. Genes do not exist in isolation, however, but interact with one another (and with the environment) to produce an organism's phenotype. What effects can these interactions have on selection?

20.4 Selection Can Be Stabilizing, Directional, or Disruptive

Although evolution is defined as changes in the genetic makeup of a population from one generation to the next, natural selection acts directly on the phenotype—that is, on the physical features expressed by an organism with a given genotype—and therefore acts only indirectly on the genotype. The reproductive contribution of a phenotype to subsequent generations relative to the contributions of other phenotypes is called its **fitness**.

fitness The contribution of a genotype or phenotype to the genetic composition of subsequent generations, relative to the contribution of other genotypes or phenotypes. (See *also* inclusive fitness.)

focus your learning

Natural selection can alter the distribution of a quantitative trait in a population over time.

Changes in reproductive rate do not necessarily change the genetic structure of a population. For example, if all individuals in a population experience the same increase in reproductive rate (during an environmentally favorable year, for instance), the genetic structure of the population will not change. Changes in numbers of offspring are responsible for increases and decreases in the *size* of a population, but only changes in the *relative* success of different phenotypes in a population will lead to changes in allele frequencies from one generation to the next. The fitness of individuals of a particular phenotype is a function of the probability of those individuals surviving multiplied by the average number of offspring they produce over their lifetimes. In other words, *the fitness of a phenotype is determined by the relative rates of survival and reproduction of individuals with that phenotype.*

Until now, we have only discussed traits influenced by alleles at a single locus. Such traits are often distinguished by discrete qualities (black versus white, or smooth versus wrinkled) and so are called **qualitative traits**. Many traits, however, are influenced by alleles at more than one locus. Such traits are likely to show *continuous* quantitative variation rather than *discrete* qualitative variation, and so are known as **quantitative traits**. For example, body size is a continuous variable; the distribution of body sizes of individuals in a population, a trait that is influenced by genes at many loci as well as by the environment, is likely to resemble a continuous bell-shaped curve.

Natural selection can act on characters with quantitative variation in any one of several different ways, producing quite different results (**Focus: Key Figure 20.12**):

(A) Stabilizing selection

(B) Directional selection

(C) Disruptive selection

Figure 20.12 Natural Selection Can Operate in Several Ways The graphs in the left-hand column show the fitness of individuals with different phenotypes for the same character. The right-hand graphs show the distribution of the phenotypes in the population before (light green) and after (dark green) the influence of selection.

Q: Why might selection for a trait in a population shift from directional to stabilizing selection over time, even if the optimal value for the trait stays constant?

Stabilizing selection preserves the average characteristics of a population by favoring average individuals.

Directional selection changes the characteristics of a population by favoring individuals that vary in one direction from the mean of the population.

Disruptive selection changes the characteristics of a population by favoring individuals that vary in both directions from the mean of the population.

stabilizing selection Selection against the extreme phenotypes in a population, so that the intermediate types are favored. (Contrast with directional selection, disruptive selection.)

directional selection Selection in which phenotypes at one extreme of the population distribution are favored. (Contrast with disruptive selection, stabilizing selection.)

disruptive selection Selection in which phenotypes at both extremes of the population distribution are favored. (Contrast with directional selection, stabilizing selection.)

Stabilizing selection reduces variation in populations

If the smallest and largest individuals in a population contribute fewer offspring to the next generation than do individuals closer to the average size, then stabilizing selection is operating on body size (see [Figure 20.12A](#)). Stabilizing selection reduces variation in populations, but it

does not change the mean. Natural selection frequently acts in this way, countering increases in variation brought about by sexual recombination, mutation, or gene flow. Rates of phenotypic change in many species are slow because natural selection is often stabilizing. Stabilizing selection operates, for example, on human birth weight. Babies who are lighter or heavier at birth than the population mean die at higher rates than babies whose weights are close to the mean ([Figure 20.13](#)). In discussions of specific genes, stabilizing selection is often called [purifying selection](#) because there is selection against any deleterious mutations to the usual gene sequence.

Figure 20.13 Human Birth Weight Is Influenced by Stabilizing Selection Babies that weigh more or less than average are more likely to die soon after birth than are babies with weights closer to the population mean.

purifying selection The elimination by natural selection of detrimental characters from a population. (Contrast with positive selection.)

Directional selection favors one extreme

Directional selection is operating when individuals at one extreme of a character distribution contribute more offspring to the next generation than other individuals do, shifting the average value of that character in the population toward that extreme. The opening story in this chapter describes directional selection for improved echolocation abilities in bats over time, and also directional selection for improved ultrasound hearing in their prey.

In the case of a single gene locus, directional selection may result in favoring a particular genetic variant—referred to as [positive selection](#) for that variant. By favoring one phenotype over another, directional selection results in an increase of the frequencies of alleles that produce the favored phenotype.

positive selection Natural selection that acts to establish a trait that enhances survival in a population. (Contrast with purifying selection.)

If directional selection operates over many generations, an evolutionary trend is seen in the population (see [Figure 20.12B](#)). Evolutionary trends often continue for many generations, but they can be reversed if the environment changes and different phenotypes are favored, or halted when an optimal phenotype is reached or trade-offs between different adaptational advantages oppose further change. The character then undergoes stabilizing selection.

The long horns of Texas Longhorn cattle ([Figure 20.14](#)) are an example of a trait that has evolved through directional selection. Texas Longhorns are descendants of cattle brought to the New World by Christopher Columbus, who picked up a few cattle in the Canary Islands and brought them to the island of Hispaniola in 1493. The cattle multiplied, and their descendants were taken to the mainland of Mexico. Spaniards exploring what would become Texas and the southwestern United States brought these cattle with them, some of which escaped and formed feral herds. Populations of feral cattle increased greatly over the next few hundred years, but there was heavy predation from bears, mountain lions, and wolves, especially on the young calves. Cows with longer horns were more successful in protecting their calves against attacks, and over a few hundred years the average horn length in the feral herds increased considerably. In addition, the cattle evolved resistance to endemic diseases of the Southwest, as well as higher fecundity and longevity. Texas Longhorns often live and produce calves well into their twenties—about twice as long as many breeds of cattle that have been artificially selected by humans for traits such as high fat content or high milk production (which are examples of artificial directional selection).

Figure 20.14 A Result of Directional Selection In the American Southwest, long horns were advantageous for defending calves from attacks by predators, so cows with longer horns were more likely to raise calves successfully. As a result, horn length in feral herds of cattle increased between the early 1500s and the 1860s, leading to the Texas Longhorn breed. This evolutionary trend has been maintained by modern ranchers practicing artificial selection.

Disruptive selection favors extremes over the mean

When disruptive selection operates, individuals at opposite extremes of a character distribution contribute more offspring to the next generation than do individuals close to the mean, which increases variation in the population (see [Figure 20.12C](#)).

The strikingly bimodal (two-peaked) distribution of bill sizes in the black-bellied seedcracker (*Pyrenestes ostrinus*), a West African finch ([Figure 20.15](#)), illustrates how disruptive selection can influence populations in nature. The seeds of two types of sedges (marsh plants) are the most abundant food source for these finches during part of the year. Birds with large bills can readily crack the hard seeds of the sedge *Scleria verrucosa*. Birds with small bills can crack *S. verrucosa* seeds only with difficulty; however, they feed more efficiently on the soft seeds of *S.*

goossensii than do birds with larger bills. Young finches whose bills deviate markedly from the two predominant bill sizes do not survive as well as finches whose bills are close to one of the two sizes represented by the distribution peaks. Because there are few abundant food sources in the finches' environment, and because the seeds of the two sedges do not overlap in hardness, birds with intermediate-sized bills are less efficient in using either one of the species' principal food sources. Disruptive selection therefore maintains a bimodal bill size distribution.

Figure 20.15 Disruptive Selection Results in a Bimodal Character Distribution

The bimodal distribution of bill sizes in the black-bellied seedcracker (*Pyrenestes ostrinus*) of West Africa is a result of disruptive selection, which favors individuals with larger and smaller bill sizes over individuals with intermediate-sized bills.

20.4 recap

Natural selection can both change and stabilize phenotypes within populations. Directional selection can result in continuous change to phenotypes; stabilizing selection slows change from a favored phenotype; and disruptive selection can result in one population that exhibits multiple distinct phenotypes.

learning outcomes

You should be able to:

- Describe the effect of each type of selection (stabilizing, directional, and disruptive) on phenotype distribution.
- Distinguish conditions in which selection is likely to be directional, stabilizing, or disruptive.

1. Describe the different expected outcomes of stabilizing, directional, and disruptive selection.
2. Why would you expect selection on human birth weight to be stabilizing rather than directional?
3. Can you think of examples of extreme phenotypes in animal or plant populations that

could be explained by directional selection?

Genetic drift, stabilizing selection, and directional selection all tend to reduce genetic variation within populations. Nevertheless, as we have seen, most populations harbor considerable genetic variation. What processes produce and maintain genetic variation within populations?

20.5 Multiple Factors Account for the Maintenance of Variation in Populations

Genetic variation is the raw material on which mechanisms of evolution act. But if favored alleles increase in frequency in populations, then why aren't other alleles always lost from the population? In this section we will discuss several factors—neutral mutations, sexual recombination, frequency-dependent selection, and heterozygote advantage—that affect how genetic variation is established, how it is distributed among individuals, and how it is maintained within populations.

focus your learning

Genetic variation is critical to the survival of a species.

Several mechanisms maintain genetic variation in populations despite selection for favored alleles.

Neutral mutations accumulate in populations

An allele that does not affect the fitness of an organism—that is, an allele that is no better or worse than alternative alleles at the same locus—is called a **neutral allele**. Neutral alleles are added to a population over time through mutation, providing the population with considerable genetic variation. The frequencies of neutral alleles are not affected directly by natural selection. Even in large populations, neutral alleles may be lost, or may increase in frequency, purely by random genetic drift.

neutral allele An allele that does not alter the functioning of the proteins for which it codes.

Much of the phenotypic variation we are able to observe is not neutral. However, modern techniques enable us to measure ***neutral variation at the molecular level** and provide the means to distinguish it from adaptive variation.

Sexual recombination amplifies the number of possible genotypes

In asexually reproducing organisms, each new individual is genetically identical to its parent unless there has been a mutation. When organisms reproduce sexually, however, offspring differ from their parents not only because they result from the combination of genetic material from two different gametes, but also through crossing over and independent assortment of chromosomes during meiosis, as described in [Key Concept 11.5](#). Sexual recombination generates an endless variety of genotypic combinations that increase the evolutionary potential of populations—a long-term advantage of sex. Although many species reproduce asexually most of the time, few are strictly asexual over long periods of evolutionary time. Almost all have some means of achieving genetic recombination.

The evolution of the mechanisms of meiosis and the evolution of sexual recombination were crucial events in the history of life. Exactly how these attributes arose is puzzling, however, because sex has at least three striking disadvantages in the short term:

- Recombination breaks up adaptive combinations of genes.

- . Sex reduces the rate at which females pass genes on to their offspring.
- . Dividing offspring into separate sexes greatly reduces the overall reproductive rate.

To see why this last disadvantage exists, consider an asexual female that produces the same number of offspring as a sexual female. Let's assume that both females produce two offspring, but that 50 percent of the sexual female's offspring will be males (and thus contribute only sperm). In this next (F_1) generation, both asexual females will produce two more offspring each, but there is only one sexual F_1 female to produce offspring. Thus the effective reproductive rate of the asexual lineage is twice that of the sexual lineage.

The evolutionary problem is to identify the advantages of sex that can overcome such short-term disadvantages. Several hypotheses have been proposed to explain the existence of sex, none of which are mutually exclusive. One is that sexual recombination facilitates repair of damaged DNA, because breaks and other errors in DNA on one chromosome can be repaired by copying the intact sequence from the homologous chromosome.

Another advantage is that sexual reproduction permits the elimination of deleterious mutations. As explained in [Key Concept 13.4](#), DNA replication is not perfect. Errors are introduced in every generation, and most of these errors result in lower fitness. Asexual organisms have no mechanism to eliminate deleterious mutations. Hermann J. Muller noted that the accumulation of deleterious mutations in a nonrecombining genome is like a genetic ratchet. The mutations accumulate—"ratchet up"—at each replication. A mutation occurs and is passed on when the genome replicates, then two new mutations occur in the next replication, so three mutations are passed on, and so on. Over time, the least-mutated class of individuals is lost from the population as new mutations occur. Deleterious mutations cannot be eliminated except by the death of the lineage or a rare back mutation. This accumulation of deleterious mutations in lineages that lack genetic recombination is known as [Muller's ratchet](#). In sexual species, by contrast, genetic recombination produces some individuals with more of these deleterious mutations and some with fewer. The individuals with fewer deleterious mutations are more likely to survive. Thus sexual reproduction allows natural selection to eliminate particular deleterious mutations from the population over time.

Muller's ratchet The accumulation— "ratcheting up"—of deleterious mutations in the nonrecombining genomes of asexual species.

Another advantage of sex is the great variety of genetic combinations it creates in each generation. Sexual recombination does not directly influence the frequencies of alleles; rather, *it generates new combinations of alleles on which natural selection can act*. It expands variation in a character influenced by alleles at many loci by creating new genotypes. For example, genetic variation can be a defense against pathogens and parasites. Most pathogens and parasites have much shorter life cycles than their hosts and can rapidly evolve counteradaptations to host defenses. Sexual recombination can give the host's defenses a chance to keep up.

Frequency-dependent selection maintains genetic variation within populations

Natural selection often preserves variation as a polymorphism (the presence of two or more variants of a character in the same population). When the fitness of a given phenotype depends on its frequency in a population, a polymorphism may be maintained by a process known as [frequency-dependent selection](#). *Perissodus microlepis*, a small fish that lives in Lake Tanganyika in East Africa, provides an example of frequency-dependent selection.

frequency-dependent selection Selection that changes in intensity with the proportion of

individuals in a population having the trait.

P. microlepis feeds on the scales of other fish, approaching its prey from behind and dashing in to bite off several scales from the prey's flank. Because of an asymmetrical jaw joint, the mouth of this scale-eating species opens either to the right or to the left; the direction is genetically determined ([Figure 20.16](#)). "Right-mouthed" individuals always attack from the victim's left, and "left-mouthed" individuals always attack from the victim's right. The distorted mouth enlarges the area of teeth in contact with the prey's flank, but only if the scale-eater attacks from the appropriate side.

Figure 20.16 A Stable Polymorphism Frequency-dependent selection maintains equal proportions of left- and right-mouthed individuals of the scale-eating fish *Perissodus microlepis*.

Prey fish are alert to approaching scale-eaters, so attacks are more likely to be successful if the prey must watch both flanks. Vigilance by prey thus favors equal numbers of right- and left-mouthed scale-eaters in a population, because if attacks from one side were more common than the other, prey fish would pay more attention to potential attacks from that side. Over an 11-year study of *P. microlepis* in Lake Tanganyika, the genetic polymorphism was found to be stable, and the two phenotypes of the scale-eaters remained at about equal frequencies.

Heterozygote advantage maintains polymorphic loci

In many cases, different alleles of a particular gene are advantageous under different environmental conditions. Most organisms experience a wide variety of environmental conditions over time. A night is dramatically different from the preceding day. A cold, cloudy day differs from a clear, hot one. Day length and temperature change seasonally. For many genes, a single allele is unlikely to perform well under all these conditions. In such cases, heterozygous individuals (with two different alleles) are likely to outperform individuals that are homozygous (with only one of those two alleles).

Colias butterflies of the Rocky Mountains live in environments where dawn temperatures are often too cold, and afternoon temperatures too hot, for the butterflies to fly. Populations of these butterflies are polymorphic for a gene that encodes the enzyme phosphoglucose isomerase (PGI), which influences how well a butterfly flies at different temperatures. Butterflies with certain PGI genotypes can fly better during the cold hours of early morning; others perform better during midday heat (**Figure 20.17**). The optimal body temperature for flight is 35°C–39°C, but some butterflies can fly with body temperatures as low as 29°C or as high as 40°C. During spells of unusually hot weather, heat-tolerant genotypes are favored; during spells of unusually cool weather, cold-tolerant genotypes are favored.

experiment

Figure 20.17A A Heterozygote Mating Advantage

Original Paper: Watt, W. B., P. A. Carter and S. M. Blower. 1985. Adaptation at specific loci. IV. Differential mating success among glycolytic allozyme genotypes of *Colias* butterflies. *Genetics* 109: 157–175.

Among butterflies of the genus *Colias*, males that are heterozygous for two alleles of the PGI enzyme can fly farther under a broader range of temperatures than males that are homozygous for either allele. Does this ability give heterozygous males a mating advantage?

HYPOTHESIS▶ Heterozygous male *Colias* will have proportionally greater mating success than homozygous males.

METHOD

1. For each of two *Colias* species, capture mated female butterflies in the field. In the laboratory, allow them to lay eggs.
2. Determine the genotypes of the females and their offspring, and thus the genotypes of the fathers.
3. Compare the frequency of heterozygotes among successfully mating males with the frequency of heterozygotes among all viable males (i.e., males captured flying with females).

RESULTS

For both species, the proportion of heterozygotes among the males that mated successfully was higher than the proportion of heterozygotes among all viable males.

CONCLUSION▶ Heterozygous *Colias* males have a mating advantage over homozygous males.

work with the data

Figure 20.17B Do Heterozygous Males Have a Mating Advantage?

Original Paper: Watt, W. B., P. A. Carter and S. M. Blower. 1985.

Ward Watt and his colleagues tested the hypothesis that males with two different alleles for the PGI enzyme (heterozygotes) were more likely to mate successfully with females than were homozygous males. They reasoned that the heterozygous males could fly farther under a broader range of temperatures than could homozygous males, and that this ability would give heterozygous males greater access to receptive females. To test this hypothesis, they needed to know the frequency of heterozygotes among successfully mating males, and they needed to compare that frequency with the frequency of heterozygotes among males in the general population (i.e., all the potential mates available to females). To estimate the frequency of heterozygotes among mating males, Watt and his colleagues collected mated female butterflies in the field and allowed them to lay eggs in the laboratory. They hatched the eggs and determined the genotypes of the offspring, as well as the genotypes of the females. Using this information, they could determine the genotypes of the males that fathered the larvae. They then compared the estimated frequency of heterozygotes among the successful fathers with the frequency of heterozygotes among all viable males in the population. Samples of their data are given in the table.

Species	All viable males ^a		Mating Males	
	Heterozygous/ total	Percent heterozygous	Heterozygous/ total	Percent heterozygous
<i>C. philodice</i>	32/74	43.2	31/50	62
<i>C. eurytheme</i>	44/92	47.8	45/59	76.3

^a "Viable males" are males captured flying with females (hence the potential to mate).

QUESTIONS

1. If we assume that the proportions of each genotype among mating males should be the same as the proportions seen among all viable males, what is the number of *mating males* expected to be heterozygous and homozygous in each sample?
2. Use a chi-square test (see Appendix B) to evaluate the significance of the difference in the observed and expected numbers of heterozygous and homozygous individuals among the mating males. The critical value ($P = 0.05$) of the chi-square distribution with one degree of freedom is 3.841. Are the observed numbers of genotypes among mating males significantly different ($P < 0.05$) from the expected numbers in these samples?
3. The investigators determined the genotypes of enough larvae from each batch of eggs to judge the genotype of the father with 99% certainty. How many larvae did they need to measure to achieve that level of certainty?
Hint: If the female is homozygous—say, genotype *ii*—the number needed is small. However, if a female is heterozygous—say, genotype *ij*—and only *ii* and *ij* progeny are found among her offspring, more larvae need to be genotyped. In this particular case, the father can be only *ii* or *ij*. If he were *ij*, the probability that any one offspring is not *ij* = 0.75, so the chance of getting only *ii* and *ij* among n offspring is 0.75^n . What value of n is required to reduce the probability of error in determining the father's genotype to 0.01?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Heterozygous *Colias* butterflies can fly over a greater range of temperatures than

homozygous individuals, which should give them an advantage in foraging and finding mates. A test of this prediction found that heterozygous males did indeed have a mating advantage, and further, that this advantage maintains the polymorphism in the population. Of course, the heterozygous genotype can never become fixed in the population, because the offspring of two heterozygotes will always include both classes of homozygotes in addition to heterozygotes.

Genetic variation within species is maintained in geographically distinct populations

Much of the genetic variation within species is preserved as differences among members living in different places (populations). Populations often vary genetically because they are subjected to different selective pressures in different environments. Some individuals of the white clover (*Trifolium repens*) produce the poisonous chemical cyanide. Poisonous individuals are less appealing to herbivores—particularly mice and slugs—than are nonpoisonous individuals. However, clover plants that produce cyanide are more likely to be killed by frost, because freezing damages cell membranes and releases cyanide into the plant's own tissues.

In European populations of *Trifolium repens*, the frequency of cyanide-producing individuals increases gradually from north to south and from east to west (Figure 20.18). A pattern of gradual change in phenotype across a geographic gradient is known as **clinal variation**. In the white clover cline, poisonous plants make up a large proportion of populations only in areas where winters are mild. Cyanide-producing individuals are rare where winters are cold, even though herbivores graze clovers heavily in those areas.

Figure 20.18 Geographic Variation in a Defensive Chemical The proportion of cyanide-producing individuals in European populations of white clover (*Trifolium repens*) depends on winter temperatures.

clinal variation [Gk. *klinein*: to lean] Gradual change in the phenotype of a species over a geographic gradient.

20.5 recap

Neutral mutations, sexual recombination, frequency-dependent selection, and heterozygote advantage all act to maintain considerable genetic variation in most populations. Variation within species is also maintained among geographically distinct populations.

learning outcomes

You should be able to:

- Explain how genetic variation is useful for a species in the face of environmental variability.
- Propose a process for the maintenance of deleterious alleles in a population and a method for testing the hypothesis.

1. Human populations in central Africa have a high frequency of sickle-cell anemia, a genetic disorder that occurs in individuals who are homozygous for a particular allele of the hemoglobin gene. Despite strong selection against the homozygous sickle-cell condition, the sickle allele is maintained in relatively high frequencies in human populations that live in areas where malaria was historically common (compare the maps below). Formulate a hypothesis that explains how this deleterious allele could be maintained in the population, even though individuals who are homozygous for the sickle allele are strongly disadvantaged.

Historic range of malaria in human populations

Distribution of sickle cell allele

2. How could you test the hypothesis that you formulated in Question 1?
3. How could the presence of a great deal of genetic variation within a population increase the chances that some members of the population would survive an unprecedented environmental change? Why is there no guarantee that this would be the case?

The mechanisms of evolution have produced a remarkable variety of organisms. There are organisms that have adapted to nearly every environment on Earth. This natural variation, along with the success of breeders attempting to produce desired traits in domesticated plants and animals, suggests that evolution can produce a wide variety of adaptive traits. But are there limits to the adaptations evolution can produce?

***connect the concepts** [Key Concept 23.2](#) describes how variation in neutral molecular traits can be used to study divergence among genes, populations, and species.

20.6 Evolution Is Constrained by History and Trade-Offs

We would be mistaken to assume that evolutionary mechanisms can produce any trait we might imagine. Evolution is constrained in many ways. Lack of appropriate genetic variation, for example, prevents the development of many potentially favorable traits. If the allele for a given trait does not exist in a population, that trait cannot evolve, even if it would be highly favored by natural selection. Most possible combinations of genes and genotypes have never existed in any population and so have never been tested under natural selection.

focus your learning

Evolutionary outcomes are limited by preexisting traits, cost-benefit trade-offs, and constraints of the natural world.

Macroevolutionary (large-scale, long-term) patterns across species sometimes require additional explanations beyond microevolutionary (small-scale, short-term) processes within populations.

In addition, constraints are imposed on organisms by the dictates of physics and chemistry. The size of cells, for example, is constrained by the stringencies of surface area-to-volume ratios (see [Figure 5.2](#)). The ways in which proteins can fold are limited by the bonding capacities of their constituent molecules (see [Key Concept 3.2](#)). And the energy transfers that fuel life must operate within the laws of thermodynamics (see [Key Concept 8.1](#)). Keep in mind that evolution works within the boundaries of these universal constraints as well as the constraints described in this section.

Developmental processes constrain evolution

As [Chapter 19](#) explained, developmental constraints on evolution are paramount *because all evolutionary innovations are modifications of previously existing structures*. Human engineers seeking to power an airplane can start “from scratch” to design a completely new type of engine (powered by jet propulsion) to replace the previous type (powered by propellers). Evolutionary changes, however, cannot happen in this way. Current phenotypes of organisms are constrained by historical conditions and past selective pressures.

A striking example of such developmental constraints is provided by the evolution of fish that spend most of their time on the sea bottom, where a ventrally flattened body is advantageous. One such lineage, the bottom-dwelling skates and rays, shares a common ancestor with sharks, whose bodies are already somewhat ventrally flattened and whose skeletal frame is made of flexible cartilage. Skates and rays evolved a body type that further flattened their bellies, allowing them to swim along the ocean floor ([Figure 20.19A](#)).

(A) *Taeniura lymma*

(B) *Bothus lunatus*

Figure 20.19 Two Solutions to a Single Problem (A) This stingray, whose ancestors were dorsoventrally flattened, lies on its belly. Stingrays' bodies are symmetrical around the dorsal backbone. **(B)** The flounder, whose ancestors were laterally flattened, lies on its side. (The backbone of this individual is at the left.) Flounders' eyes migrate during development so that both are on the same side of the body.

By contrast, plaice, sole, and flounder are bottom-dwelling descendants of deep-bellied, laterally flattened ancestors with bony skeletons. The only way these fish can lie flat is to flop over on their sides. Their ability to swim is thus curtailed, but their bodies can lie still and are well camouflaged. During development, one eye of these flatfishes moves so that both eyes are positioned on the same side of the body ([Figure 20.19B](#)). Such shifts in eye position have evolved several times, and shifts have happened in both directions (that is, both left- and right-eyed flatfish have evolved independently). Small shifts in the position of one eye probably helped ancestral flatfish see better, resulting in the body forms found today. This path to producing a flattened body may not be optimal, but the fishes' developmental capabilities constrain the pathways that evolution can take.

Trade-offs constrain evolution

Adaptations frequently impose both costs and benefits. For an adaptation to be favored, the fitness benefits it confers must exceed the fitness costs it imposes—in other words, the **trade-off** must be worthwhile. For example, there are metabolic costs associated with developing and maintaining certain conspicuous features (such as antlers or horns) that males use to compete with other males for access to females. The fact that these features are common in many species suggests that the benefits derived from possessing them must outweigh the costs.

trade-off The relationship between the fitness benefits conferred by an adaptation and the fitness costs it imposes. For an adaptation to be favored by natural selection, the benefits must exceed the costs.

As a result of trade-offs, many traits that are adaptive in one context may be maladaptive in another. Consider the rough-skinned newt and one of its predators, the common garter snake ([Figure 20.20A](#)). The newt sequesters a potent neurotoxin called tetrodotoxin (TTX) in its skin. TTX paralyzes nerves and muscles by blocking sodium channels (see [Key Concept 44.3](#)). Most vertebrates—including many garter snakes—will die if they eat a rough-skinned newt. But some garter snakes can eat rough-skinned newts and survive: TTX-resistant sodium channels have evolved in the nerves and muscles of such individuals. However, for several hours after eating a newt, TTX-resistant snakes can move only slowly, and they never move as fast as nonresistant snakes. Resistant snakes are thus more vulnerable to their own predators than are TTX-sensitive snakes. This vulnerability leads to selection *against* TTX-resistant sodium channels in garter snake populations that occur outside the range of rough-skinned newts, even though there is selection *for* TTX resistance in many areas where newts are present ([Figure 20.20B](#)).

(A)

Figure 20.20 Resistance to a Toxin Comes at a Cost (A) Garter snakes (*Thamnophis sirtalis*) prey on rough-skinned newts (*Taricha granulosa*). Rough-skinned newts defend themselves by sequestering a neurotoxin, TTX, in their skin. In turn, TTX-resistant sodium channels have evolved in some snake populations, allowing the snakes to eat toxic newts but resulting in slower movement by the snakes. **(B)** High TTX resistance in garter snakes is found only in regions where snake and newt populations overlap (tan area).

Q: Why doesn't TTX resistance spread throughout the range of the garter snake?

Animation 20.2 Assessing the Costs of Adaptation www.Life11e.com/a20.2

Short-term and long-term evolutionary outcomes sometimes differ

The short-term changes in allele frequencies within populations that we have emphasized in this chapter, often termed **microevolutionary** changes, are an important focus of study for evolutionary biologists. These changes can be observed directly, they can be manipulated experimentally, and they demonstrate the actual processes by which evolution occurs.

microevolution Evolutionary changes below the species level, affecting allele frequencies. (Contrast with macroevolution.)

Long-term patterns of **macroevolutionary** change can also be strongly influenced by events that occur so infrequently (such as a meteorite impact) or so slowly (such as continental drift) that they are unlikely to be observed during short-term studies. The evolutionary mechanisms at work may change over time with changing environmental conditions. Even among the descendants of a single ancestral species, different lineages may evolve in different directions. Additional types of evidence—evidence demonstrating the effects of rare and unusual events on

trends in the fossil record—must be gathered if we wish to understand the course of evolution over billions of years. We will consider these long-term aspects of evolution in the remaining chapters of this section.

macroevolution [Gk. *makros*: large] Evolutionary changes occurring over long time spans and usually involving changes in many traits. (Contrast with microevolution.)

20.6 recap

Developmental processes constrain evolution because all evolutionary innovations are modifications of previously existing structures. An adaptation can evolve only if the fitness benefits it confers exceed the fitness costs it imposes.

learning outcomes

You should be able to:

- Formulate a hypothesis to explain why potentially highly advantageous phenotypes might not evolve.
- Describe an example illustrating a macroevolutionary pattern that is not easily explained by micro-evolutionary processes.

1. The largest living adult insects weigh less than 75 g (less than the weight of a relatively small songbird, such as a starling). Many flying birds are much larger than any insect, so clearly flight alone does not constrain the current size of insects. Formulate a hypothesis for why there are no giant insects presently roaming Earth.
2. Natural selection results in gradual changes *within* species over long periods of time. Describe an event that could result in significant and sudden changes across many species simultaneously.

investigatinglife

How do complex traits like echolocation, or the ability to avoid detection from echolocation, evolve in the first place?

In the opening story of this chapter, we discussed the evolutionary arms race between echolocating bats and the moths that evolved the ability to detect bat ultrasounds, and then avoid the predators. Moths are not the only potential prey of bats that have evolved the ability to hear ultrasounds. Many other groups of insects can hear the sounds produced by bats, and act to avoid these predators. In many cases, the insects can already hear, as they have evolved complex communication systems to attract mates. This produces the natural variation in the trait (hearing) that is needed for natural selection to act.

As we learned in the experiment discussed in Investigating Life: Do Long Wing Tails Help Moths Escape Bat Predation?, many non-hearing insects have evolved other strategies for confusing or avoiding echolocating bats. Several species of moths have evolved long extensions of their wings, called wing tails. The wing tails flutter as the moths fly, and the fluttering wing tails serve to distract the echolocating bats. A bat that attacks the long wing tail of a moth may get nothing but a tiny piece of moth wing, while the moth survives the attack.

Some bats locate their prey using the sounds produced by the prey themselves. There are species of bats that locate prey by the sound of calling frogs, insects, or even the ripples made by fish on the surface of the water. These prey species often must limit or modify the sounds they produce to balance the benefits of producing a sound with the costs associated with bat predation.

Species rarely evolve to a state of perfection and then stop evolving. Prey species are constantly evolving new ways to avoid predation, so predator species must evolve improved means of capturing prey. Although there are often historical, physiological, or mechanical limits to what can evolve, species are constantly changing in response to changes in their physical environment and species interactions. This constant selection for change, over millions or even billions of years, has produced the enormous diversity of life we see on Earth.

Future directions

Bats are not the only animals that have evolved the ability to echolocate. Toothed whales and dolphins, as well as some burrowing shrews and cave-dwelling birds, also use echolocation to “see” their environment with sound. So echolocation has evolved repeatedly in species that live in environments in which sight is limited. But how does a trait like echolocation first begin to evolve in a species? Some rudimentary form of the trait has to be present before selection can act to refine this sensory mode. Often, species co-opt a trait that evolved for other purposes, and then selection refines it over time for a new purpose.

Most humans do not use echolocation. We rely heavily on sight, and most of us feel awkward moving around unfamiliar spaces in the dark. But what would happen if humans were forced to live in an environment where we could not see? We already hear, of course, so we have a system that could be co-opted for echolocation. We are also capable of making sounds. Echolocation simply requires the production of sounds, the ability to detect the reflected sounds, and the ability to process the information appropriately. Indeed, some blind humans have trained themselves to use echolocation to sense their environment (see [Media Clip 20.4](#)). An individual learning a behavior is not the same as evolution of a behavior within a species, however. Before natural selection can act, there has to be genetic variation in the population for the trait in question. The fact that a few humans are able to use simple forms of echolocation shows that variation for this trait is already present in our species. The same is true for many species, which is why it is not surprising that echolocation has evolved multiple times in species that live or feed in the dark.

Media Clip 20.4 **Human Echolocation** www.Life11e.com/mc20.4

▶ 20.1 Evolution Is Both Factual and the Basis of Broader Theory

- **Evolution** is genetic change in populations over time. Evolution can be observed directly in living populations as well as in the fossil record of life.

evolution Any gradual change. Most often refers to organic or Darwinian evolution, which is the genetic and resulting phenotypic change in populations of organisms from generation to generation. (See macroevolution, microevolution. Contrast with speciation.)

- **Evolutionary theory** refers to our understanding of the mechanisms of evolutionary change.

evolutionary theory The understanding and application of the mechanisms of evolutionary change to biological problems.

- Charles Darwin is best known for his ideas on the common ancestry of divergent species and on **natural selection** (the differential survival and reproduction of individuals based on variation in their traits) as a mechanism of evolution. See [Animation 20.1](#), [Activity 20.1](#)

natural selection The differential contribution of offspring to the next generation by various genetic types belonging to the same population. The mechanism of evolution proposed by Charles Darwin.

- Since Darwin's time, many biologists have contributed to the development of evolutionary theory, and rapid progress in our understanding continues today.

▶ 20.2 Mutation, Selection, Gene Flow, Genetic Drift, and Nonrandom Mating Result in Evolution

- Mutation is the source of the genetic variation on which mechanisms of evolution act. [Review Figure 20.3](#)
- The term **adaptation** refers both to a trait that evolves through natural selection and to the process that produces such traits.

adaptation (a dap tay' shun) (1) In evolutionary biology, a particular structure, physiological process, or behavior that makes an organism better able to survive and reproduce. Also, the evolutionary process that leads to the development or persistence of such a trait. (2) In sensory neurophysiology, a sensory cell's loss of sensitivity as a result of repeated stimulation.

- Within populations, selection acts to increase the frequency of beneficial alleles and to decrease the frequency of deleterious alleles. [Review Figure 20.6](#), [Investigating Life: Do Long Wing Tails Help Moths Escape Bat Predation?](#), [Activity 20.2](#)

- Movement of individuals or gametes between populations results in **gene flow**.
- In small populations, **genetic drift**—the random loss of individuals and the alleles they possess from one generation to the next—may produce large changes in allele frequencies over time and greatly reduce genetic variation. See [Activity 20.3](#)

genetic drift Changes in gene frequencies from generation to generation as a result of random (chance) processes.

- **Population bottlenecks** occur when only a few individuals survive a random event, resulting in a drastic shift in allele frequencies within the population and the loss of genetic variation. Similarly, a population established by a small number of individuals colonizing a new region may lose genetic variation via a **founder effect**. **Review Figure 20.7**

population bottleneck A period during which only a few individuals of a normally large population survive.

founder effect Random changes in allele frequencies resulting from establishment of a population by a very small number of individuals.

- Nonrandom mating may result in changes in genotype and allele frequencies in a population.
- **Sexual selection** results from differential reproductive success based on individuals' phenotypes. **Review Figure 20.9**

sexual selection Selection by one sex of characteristics in individuals of the opposite sex. Also, the favoring of characteristics in one sex as a result of competition among individuals of that sex for mates.

▶ 20.3 Evolution Can Be Measured by Changes in Allele Frequencies

- Allele frequencies measure the amount of genetic variation in a population. Genotype frequencies show how a population's genetic variation is distributed among its members. Together, allele and genotype frequencies describe a population's **genetic structure**. **Review Figure 20.10**

genetic structure The frequencies of different alleles at each locus and the frequencies of different genotypes in a Mendelian population.

- **Hardy–Weinberg equilibrium** predicts genotype frequencies from allele frequencies in the absence of evolution. Deviation from these frequencies indicates that evolutionary mechanisms are at work. **Review Figure 20.11, Activity 20.4**

Hardy–Weinberg equilibrium In a sexually reproducing population, the allele frequency at a given locus that is not being acted on by agents of evolution; the conditions that would result in no evolution in a population.

▶ 20.4 Selection Can Be Stabilizing, Directional, or Disruptive

- Natural selection can act on characters with quantitative variation in several different ways. **Review Focus: Key Figure 20.12**
- **Stabilizing selection** acts to reduce variation without changing the mean value of a trait. **Review Figure 20.13**

stabilizing selection Selection against the extreme phenotypes in a population, so that the intermediate types are favored. (Contrast with directional selection, disruptive selection.)

- **Directional selection** acts to shift the mean value of a trait toward one extreme. **Review Figure 20.14**

directional selection Selection in which phenotypes at one extreme of the population distribution are favored. (Contrast with disruptive selection, stabilizing selection.)

- **Disruptive selection** favors both extremes of a trait value, resulting in a bimodal character distribution. **Review Figure 20.15**

disruptive selection Selection in which phenotypes at both extremes of the population distribution are favored. (Contrast with directional selection, stabilizing selection.)

► 20.5 Multiple Factors Account for the Maintenance of Variation in Populations

- Neutral mutations, sexual recombination, frequency-dependent selection, and heterozygote advantage can all maintain genetic variation within populations.
- **Neutral alleles** do not affect the fitness of an organism, are not affected by natural selection, and may accumulate or be lost by genetic drift.

neutral allele An allele that does not alter the functioning of the proteins for which it codes.

- Despite its short-term disadvantages, sexual reproduction generates countless genotypic combinations that increase the evolutionary potential and survivorship of populations.
- A polymorphism may be maintained by **frequency-dependent selection** when the fitness of a genotype depends on its frequency in a population. **Review Figure 20.16**

frequency-dependent selection Selection that changes in intensity with the proportion of individuals in a population having the trait.

- A polymorphism may also be maintained by heterozygote advantage when the fitness of the heterozygote exceeds the fitness of either homozygote. **Review Figure 20.17**
- Genetic variation within species may be maintained by the existence of genetically distinct populations over geographic space. A gradual change in phenotype across a geographic gradient is known as **clinal variation**. **Review Figure 20.18**

clinal variation [Gk. *klinein*: to lean] Gradual change in the phenotype of a species over a geographic gradient.

▶ 20.6 Evolution Is Constrained by History and Trade-Offs

- Developmental processes constrain evolution because all evolutionary innovations are modifications of previously existing structures. **Review** [Figure 20.19](#)
- Most adaptations impose costs as well as benefits. An adaptation can evolve only if the benefits it confers exceed the costs it imposes. **Review** [Figure 20.20](#), [Animation 20.2](#)

Review

- 0.1 Evolution is directly observable and is a universal principle of life.¹
- 0.2 Evolution is the result of five major processes: mutation, natural selection, gene flow, genetic drift, and nonrandom mating.

Anoles, an abundant and diverse group of lizards in the American tropics and subtropics, are common subjects of ecological and evolutionary studies. The Carolina (or green) anole, *Anolis carolinensis* ([Figure A](#)), is the only anole native to the southeastern United States. The Cuban brown anole, *Anolis sagrei* ([Figure B](#)), was introduced into south Florida in the late 1800s and has been expanding its range northward since then. When living alone, *A. carolinensis* occupies habitats from ground level to treetops, whereas *A. sagrei* lives on the ground and lower perches. The two species compete, and the more aggressive *A. sagrei* displaces *A. carolinensis* from its preferred perches. Where the two species live together, *A. carolinensis* is restricted to high treetops.

Figure A

Figure B

Across species of *Anolis*, there is a strong association between perch height and the structure of the toe pads that the lizards use to cling to branches ([Figure C](#)). Researchers wondered if the shift in perching habitat would lead to rapid evolutionary change in the toe pads of displaced *A. carolinensis* populations. In 1995, researchers deliberately introduced populations of *A. sagrei* onto islands that previously supported only populations of *A. carolinensis*, then followed the evolutionary changes in the lizard populations over the next 15 years. Researchers examined the size of the toe pads, and the number of expanded scales with adhesive bristles (lamellae) on each pad. Other islands continued to support only *A. carolinensis*.

Figure C

In 2010, the researchers measured toe-pad size and the number of lamellae on *A. carolinensis* lizards collected from both sets of islands (with and without *A. sagrei*) (**Figures D, E**). The researchers also raised offspring of lizards from these islands in a “common garden experiment,” which uses a common, controlled environment to confirm that any differences between the populations have a genetic basis.

Questions

1. What is the evidence for toe-pad evolution in the populations of *A. carolinensis* on the invaded islands? Why have toe pads in these populations of *A. carolinensis* changed so rapidly?
2. Why was the common garden experiment needed? How would the conclusions of the study have been different if the observed differences in the wild populations were not also evident in the lizards raised in a common, controlled environment?
3. Which evolutionary process or processes are most likely to explain the observed evolutionary changes? Which processes do you think are less important, and why?
4. Describe the ways that these populations of *A. carolinensis* deviate from assumptions of Hardy–Weinberg equilibrium (the conditions that would be necessary for the populations to *not* evolve).
5. Instead of *A. sagrei*, suppose another species of *Anolis* had been introduced to the Florida islands. Suppose this lizard were an aggressive treetop specialist that excluded *A. carolinensis* from the highest perches and restricted it to the ground and low perches. In this case, how would you expect the displaced

populations of *A. carolinensis* to have evolved?

investigatinglife

Using Phylogeny to Improve a Genetic Tool

Green fluorescent protein (GFP) was discovered in 1962 when Osamu Shimomura led a team that was able to purify the protein from the tissues of the bioluminescent jellyfish *Aequorea victoria*. Some 30 years after GFP's initial discovery, Martin Chalfie had the idea (and the technology) to link the gene for GFP to other protein-coding genes so that the expression of specific genes of interest could be visualized in glowing green within cells and tissues of living organisms (see [Figure 18.4](#)). This work was extended by Roger Tsien, who changed some of the amino acids within GFP to create fluorescent proteins of several distinct colors. Different-colored fluorescent proteins meant that the expression of several different proteins could be visualized and studied in the same organism at the same time. These three scientists were awarded the 2008 Nobel Prize in Chemistry for the isolation and development of GFP for visualizing gene expression.

Tsien was able to produce different-colored proteins, but he could not produce a *red* protein. This was frustrating; a red fluorescent protein would be particularly useful to biologists because red light penetrates tissues more easily than do other colors. Tsien's work stimulated Mikhail Matz to look for new fluorescent proteins in corals. Among the different coral species he studied, Matz found coral proteins that fluoresced in various shades of green, cyan (blue-green)-and red.

How had fluorescent red pigments evolved among the corals, given that the necessary molecular changes had eluded Tsien? To answer this question, Matz sequenced the genes of the fluorescent proteins and used these sequences to reconstruct the evolutionary history of the amino acid changes that produced different colors in different species of corals.

Matz's work showed that the ancestral fluorescent protein in corals was green, and that red fluorescent proteins evolved in a series of gradual steps. His analysis of evolutionary relationships allowed him to retrace these steps. Such an evolutionary history, as depicted in a tree of relationships among lineages, is called a phylogeny.

The evolution of many aspects of an organism's biology can be studied using phylogenetic methods. This information is used in all fields of biology to understand the structure, function, and behavior of organisms.

How are phylogenetic methods used to resurrect protein sequences from extinct organisms?

21.1 All of Life Is Connected through Its Evolutionary History

The sequencing of complete genomes from many diverse species has confirmed what biologists have long suspected: all of life is related through a common ancestor. The common ancestry of life explains why the general principles of biology apply to all organisms. Thus we can learn much about how the human genome works by studying the biology of model organisms because we share a common evolutionary history with those organisms. The evolutionary history of these relationships is known as **phylogeny**, and a **phylogenetic tree** is a diagrammatic reconstruction of that history.

phylogeny (fy loj' e nee) [Gk. *phylon*: tribe, race + *genesis*: source] The evolutionary history of a particular group of organisms or their genes.

phylogenetic tree A graphic representation of these lines of evolutionary descent.

focus your learning

Phylogenetic trees represent evolutionary relationships.

Phylogenies enable biologists to compare organisms and make predictions and inferences based on similarities and differences in traits.

Only homologous traits are used in reconstructing phylogenetic trees.

Phylogenetic trees are commonly used to depict the evolutionary history of species, populations, and genes. For many years such trees have been constructed based on physical structures, behaviors, and biochemical attributes. Now, as genomes are sequenced for more and more organisms, biologists are able to reconstruct the history of life in ever greater detail.

In [Chapter 20](#) we discussed why we expect populations of organisms to evolve over time. We call a series of ancestor and descendant populations a **lineage**, which we can depict as a line drawn on a time axis, as shown in [Figure 21.1](#). What happens when a single lineage divides into two? For example, a geographic barrier may divide an ancestral population into two descendant populations that no longer interbreed with one another. We depict such an event as a split, or **node**, in a phylogenetic tree (see [Figure 21.1](#)). Each of the descendant populations gives rise to a new lineage, and as these independent lineages evolve, new traits arise in each. As the lineages continue to split over time, this history can be represented in the form of a branching tree that can be used to trace the evolutionary relationships from the ancient common ancestor of a group of species, through the various lineage splits, up to the present populations of the organisms.

lineage A series of populations, species, or genes descended from a single ancestor over evolutionary time.

node [L. *nodus*: knob, knot] (1) In plants, a (sometimes enlarged) point on a stem where a leaf is or was attached. (2) A region at the anterior end of the primitive groove—the site of ingression of cells during gastrulation. In mammals and birds it serves a function similar to the

Figure 21.1 The Components of a Phylogenetic Tree Evolutionary relationships among organisms can be represented in a treelike diagram.

A phylogenetic tree may portray the evolutionary history of all life forms. Phylogenetic trees can also depict the history of a major evolutionary group (such as the insects) or of a much smaller group of closely related species. In some cases, phylogenetic trees are used to show the history of individuals, populations, or genes within a species. The common ancestor of all the organisms in the tree forms the **root** of the tree.

root The organ responsible for anchoring the plant in the soil, absorbing water and minerals, and producing certain hormones. Some roots are storage organs.

The depictions of phylogenetic trees in this book are rooted at the left, with time flowing from left (earliest) to right (most recent) (**Focus: Key Figure 21.2A**). The timing of splitting events in lineages is shown by the position of nodes on a time axis. These splits represent events where one lineage diverged into two, such as a speciation event (for a tree of species), a gene duplication event (for a tree of genes), or a transmission event (for a tree of viral lineages transmitted through a host population). The time axis may have an explicit scale, or it may simply show the relative timing of divergence events.

focus: key figure

(A)

(B)

Figure 21.2 How to Read a Phylogenetic Tree (A) Phylogenetic trees can be produced with time scales, as shown here, or with no indication of time. If no time scale is shown, then the trees are only meant to depict the relative order of

divergence events. **(B)** Lineages can be rotated around a given node, so the vertical order of taxa is largely arbitrary.

In this book's illustrations, the order in which nodes are placed along the horizontal (time) axis has meaning, but the vertical distance between the branches does not. Vertical distances have been adjusted for legibility and clarity of presentation; they do not correlate with the degree of similarity or difference among groups. Note too that lineages can be rotated around nodes in the tree, so the vertical order of lineages is also largely arbitrary (**Focus: Key Figure 21.2B**). The important information in the tree is the branching order along the time axis, as this indicates when the various lineages last shared a common ancestor.

Any group of species that we designate with a name is a **taxon** (plural *taxa*). Examples of familiar taxa include humans, primates, mammals, and vertebrates; in this series, each taxon is also a member of the next, more inclusive taxon. Any taxon that consists of all the evolutionary descendants of a common ancestor is called a **clade**. Clades can be identified by picking any point on a phylogenetic tree and from that point tracing all the descendant lineages to the tips of the terminal branches (**Figure 21.3**). Two species that are each other's closest relatives are called **sister species**. Similarly, any two clades that are each other's closest relatives are **sister clades**.

taxon (plural: taxa) [Gk. *taxis*: put in order] A biological group (typically a species or a clade) that is given a name.

clade [Gk. *klados*: branch] A monophyletic group made up of an ancestor and all of its descendants.

sister species Two species that are each other's closest relatives.

sister clades Two clades that are each other's closest relatives.

Figure 21.3 Clades Represent an Ancestor and All of Its Evolutionary Descendants All clades are subsets of larger clades, with all of life as the most inclusive taxon. In this example, the groups called mammals, amniotes, tetrapods, and vertebrates represent successively larger clades. Only a few species within each clade are represented on the tree.

Before the 1980s, phylogenetic trees tended to be seen only in the literature on evolutionary biology, especially in the area of [systematics](#)—the study and classification of biodiversity. But almost every journal in the life sciences published during the last few years contains phylogenetic trees. Trees are widely used in molecular biology, biomedicine, physiology, behavior, ecology, and virtually all other fields of biology. Why have phylogenetic studies become so widespread?

systematics The scientific study of the diversity and relationships among organisms.

Phylogenetic trees are the basis of comparative biology

In biology we study life at all levels of organization—from genes, cells, organisms, populations, and species to the major divisions of life. In most cases, however, no individual gene or organism (or other unit of study) is exactly like any other gene or organism that we investigate.

Consider the individuals in your biology class. We recognize each person as an individual human, but we know that no two are exactly alike. If we knew everyone's family tree in detail, the genetic similarity of any pair of students would be more predictable. We would find that more closely related students have many more traits in common (from the color of their hair to their

susceptibility or resistance to diseases). Likewise, biologists use phylogenies to make comparisons and predictions about shared traits across genes, populations, and species.

The evolutionary relationships among species, as represented in the [tree of life](#), form the basis for biological classification. Biologists estimate that there are tens of millions of species on Earth. So far, however, only about 1.8 million species have been classified—that is, formally described and named. New species are being discovered all the time and phylogenetic analyses are constantly reviewed and revised, so our knowledge of the tree of life is far from complete. Yet knowledge of evolutionary relationships is essential for making comparisons in biology, so biologists build phylogenies for groups of interest as the need arises. The tree of life's evolutionary framework allows us to make many predictions about the behavior, ecology, physiology, genetics, and morphology of species that have not yet been studied in detail.

tree of life A term that encompasses the evolutionary history of all life, or a graphic representation of that history.

When biologists compare species, they observe traits that differ within the group of interest and try to understand when these traits evolved. In many cases, investigators are interested in how the evolution of a trait relates to environmental conditions or selective pressures. For instance, scientists have used phylogenetic analyses to discover changes in the genome of human immunodeficiency viruses (HIVs) that result in resistance to particular drug treatments. The association of a particular genetic change in HIV with a particular treatment provides a hypothesis about the evolution of resistance that can be tested experimentally.

Any features shared by two or more species that have been inherited from a common ancestor are said to be [homologous](#). Homologous features may be any heritable traits, including DNA sequences, protein structures, anatomical structures, and even some behavior patterns. For example, all living vertebrates have a vertebral column, as did the ancestral vertebrate. Therefore the vertebral column is judged to be homologous in all vertebrates.

homology (ho mol' o jee) [Gk. *homologia*: of one mind, agreement] A similarity between two or more features that is due to inheritance from a common ancestor. The structures are said to be **homologous**, and each is a **homolog** of the others.

Derived traits provide evidence of evolutionary relationships

In tracing the evolution of a character, biologists distinguish between ancestral and derived traits. Each character of an organism evolves from one condition (the [ancestral trait](#)) to another condition (the [derived trait](#)). Derived traits that are shared among a group of organisms and are also viewed as evidence of the common ancestry of the group are called [synapomorphies](#) (*syn*, “shared”; *apo*, “derived”; *morph*, “form,” referring to the “form” of a trait). Thus the vertebral column is considered a synapomorphy—a shared, derived trait—of the vertebrates. (The ancestral trait was an undivided supporting rod.)

ancestral trait The trait originally present in the ancestor of a given group; may be retained or changed in the descendants of that ancestor.

derived trait A trait that differs from the ancestral trait. (Contrast with synapomorphy.)

synapomorphy A trait that arose in the ancestor of a phylogenetic group and is present (sometimes in modified form) in all of its members, thus helping to delimit and identify that group. Also called a shared derived trait. (Contrast with derived trait.)

Not all similar traits are evidence of relatedness. Similar traits in unrelated groups of organisms can develop for either of the following reasons:

Superficially similar traits may evolve independently in different lineages, a phenomenon called **convergent evolution**. For example, although the *wing bones* of bats and birds are homologous, having been inherited from a common tetrapod ancestor, the *wings* of bats and birds are not homologous because they evolved independently from the forelimbs of different nonflying ancestors (**Figure 21.4**). Functionally similar structures that have independent evolutionary origins are called **analogous** characters.

convergent evolution Independent evolution of similar features from different ancestral traits.

analogous In biology, refers to similar structures found in two or more groups of organisms, but with separate, independent evolutionary origins. An example is the wings of bats and the wings of birds, which evolved independently as wings from wingless ancestors.

Figure 21.4 The Bones Are Homologous, the Wings Are Not The supporting bone structures of both bat wings and bird wings are derived from a common four-limbed ancestor and are thus homologous. However, the wings themselves—an adaptation for flight evolved independently in the two groups.

A character may revert from a derived state back to an ancestral state in an event called an **evolutionary reversal**.

evolutionary reversal The reappearance of an ancestral trait in a group that had previously acquired a derived trait.

For example, the derived limbs of terrestrial tetrapods evolved from the ancestral fins of their aquatic ancestors. Then, within the mammals, the ancestors of modern cetaceans (whales and

olphins) returned to the ocean, and cetacean limbs evolved to once again resemble their ancestral state—fins. The superficial similarity of cetacean and fish fins does not suggest a close relationship between these groups. Instead, the similarity arises from evolutionary reversal.

Similar traits generated by convergent evolution and evolutionary reversals are called homoplastic traits or [homoplasies](#).

homoplasy (home' uh play zee) [Gk. *homos*: same + *plastikos*: shape, mold] The presence in multiple groups of a trait that is not inherited from the common ancestor of those groups. Can result from convergent evolution, evolutionary reversal, or parallel evolution.

 Media Clip 21.1 **Morphing Arachnids** www.Life11e.com/mc21.1

A particular trait may be ancestral or derived, depending on our point of reference. For example, all birds have feathers. We infer from this that feathers (which are highly modified scales) were present in the common ancestor of modern birds. Therefore we consider the presence of feathers to be an ancestral trait for any particular group of modern birds, such as the songbirds. However, feathers are not present in any other living animals. In reconstructing a phylogeny of all living vertebrates, the presence of feathers is a derived trait found only among birds, and thus is a synapomorphy of the birds.

21.1 recap

A phylogenetic tree is a description of evolutionary relationships among organisms or their genes. All living organisms share a common ancestor and are related through the phylogenetic tree of life.

learning outcomes

You should be able to:

- Draw and label the parts of a phylogenetic tree and explain the biological interpretation of each part.
- Make inferences and predictions about evolutionary groups based on a phylogenetic tree.
- Explain how homoplasies (convergences and reversals of character states) are accounted for when reconstructing phylogenetic relationships.

1. What biological processes are represented in a phylogenetic tree?
2. Why is it important to consider only homologous characters in constructing phylogenetic trees?
3. What are some reasons that similar traits might arise independently in species that are only distantly related? Can you think of examples among familiar organisms? How do biologists account for these homoplasies in reconstructing phylogenies?

Phylogenetic analyses have become increasingly important to many types of biological research in recent years, and they are the basis for the comparative nature of biology. For the most part, however, evolutionary history cannot be observed directly. How, then, do biologists reconstruct the past? One way is by using phylogenetic analyses to construct a tree.

21.2 Phylogeny Can Be Reconstructed from Traits of Organisms

To illustrate how a phylogenetic tree is constructed, consider the eight vertebrate animals listed in [Table 21.1](#): lamprey, perch, salamander, lizard, crocodile, pigeon, mouse, and chimpanzee. We will initially assume that any given derived trait arose only once during the evolution of these animals (that is, there has been no convergent evolution), and that no derived traits were lost from any of the descendant groups (there has been no evolutionary reversal). For simplicity, we have selected traits that are either present (+) or absent (-).

table 21.1 Eight Vertebrates and the Presence or Absence of Some Shared Derived Traits

Taxon	Jaws	Lungs	Claws or nails	Gizzard	Feathers	Fur	Mammary glands	Keratinous scales
Lamprey (outgroup)	-	-	-		--	-	-	-
Perch	+	-	-		-	-	-	-
Salamander	+	+	-		-	-	-	-
Lizard	+	+	+		-	-	-	+
Crocodile	+	+	+		-	-	-	+
Pigeon	+	+	+		+	-	-	+
Mouse	+	+	+		-	+	+	-
Chimpanzee	+	+	+		-	+	+	-

focus your learning

Modern phylogenetic methods employ the principle of parsimony and mathematical models (when appropriate) to analyze morphological, developmental, paleontological, behavioral, and molecular data.

In a phylogenetic study, the group of organisms of primary interest is called the [ingroup](#). As a point of reference, an ingroup is compared with an [outgroup](#): a species or group that is closely related to the ingroup but is known to be phylogenetically outside it. In other words, the root of the tree is located between the ingroup and the outgroup. Any trait that is present in both the ingroup and the outgroup must have evolved before the origin of the ingroup and thus must be ancestral for the ingroup. In contrast, traits that are present in only some members of the ingroup must be derived traits within that ingroup. As we will see in [Chapter 32](#), a group of jawless fish called the lampreys is thought to have separated from the lineage leading to the other vertebrates before the jaw arose. Therefore we have included the lamprey as the outgroup for our analysis. Because derived traits are traits acquired by other members of the vertebrate lineage *after* they diverged from the outgroup, any trait that is present in both the lamprey and the other vertebrates is judged to be ancestral.

ingroup
In a phylogenetic study, the group of organisms of primary interest. (Contrast with

outgroup.)

outgroup In phylogenetics, a group of organisms used as a point of reference for comparison with the groups of primary interest (the ingroup).

We begin by noting that the chimpanzee and mouse share two traits—mammary glands and fur—that are absent in both the outgroup and in the other species of the ingroup. Therefore we infer that mammary glands and fur are derived traits that evolved in a common ancestor of chimpanzees and mice after that lineage separated from the lineages leading to the other vertebrates. These characters are synapomorphies that unite chimpanzees and mice (as well as all other mammals, although we have not included other mammalian species in this example). By the same reasoning, we can infer that the other shared derived traits are synapomorphies for the various groups in which they are expressed. For instance, keratinous scales are a synapomorphy of the lizard, crocodile, and pigeon.

[Table 21.1](#) also tells us that, among the animals in our ingroup, the pigeon has a unique trait: feathers. Feathers are a synapomorphy of birds and their extinct relatives. However, because we only have one bird in this example, the presence of feathers provides no clues concerning relationships among these eight species of vertebrates. However, gizzards are found in both birds and crocodiles, so this trait is evidence of a close relationship between birds and crocodilians.

By combining information about the various synapomorphies, we can construct a phylogenetic tree. We infer from our information that mice and chimpanzees—the only two animals that share fur and mammary glands—share a more recent common ancestor with each other than they do with pigeons and crocodiles. Otherwise we would need to assume that the ancestors of pigeons and crocodiles also had fur and mammary glands but subsequently lost them. There is no need to make these additional assumptions.

[Figure 21.5](#) shows a phylogenetic tree for the vertebrates in [Table 21.1](#), based on the shared derived traits we examined. This particular tree was easy to construct because it is based on a very small sample of traits, and the derived traits we examined evolved only once and were never lost after they appeared. Had we included a snake in the group, our analysis would not have been as straightforward. We would have needed to examine additional characters to determine that snakes evolved from a group of lizards that had limbs. In fact, the analysis of many characters shows that snakes evolved from burrowing lizards that became adapted to a subterranean existence.

Figure 21.5 Constructing a Phylogenetic Tree This phylogenetic tree was constructed from the information in [Table 21.1](#) using the parsimony principle. Each clad in the tree is supported by at least one shared derived trait, or synapomorphy.

Activity 21.1 Constructing a Phylogenetic Tree www.Life11e.com/ac21.1

Parsimony provides the simplest explanation for phylogenetic data

The phylogenetic tree shown in [Figure 21.5](#) is based on only a very small sample of traits. Typically, biologists construct phylogenetic trees using hundreds or thousands of traits. With larger data sets, we would expect to observe traits that have changed more than once, and thus would expect to see convergence and evolutionary reversal. How do we determine which traits are synapomorphies and which are homoplasies? One way is to invoke the principle of parsimony.

Activity 21.2 Phylogeny and Molecular Evolution Simulation www.Life11e.com/ac21.2

In its most general form, the **parsimony principle** states that the preferred explanation of observed data is the simplest explanation. Applying the principle of parsimony to the reconstruction of phylogenies entails minimizing the number of evolutionary changes that need to be assumed over all characters in all groups in the tree. In other words, the best hypothesis under the parsimony principle is one that requires the fewest homoplasies. This application of parsimony is a specific case of a general principle of reasoning called Occam's razor: the best explanation is the one that best fits the data while making the fewest assumptions. More complicated explanations are accepted only when the evidence requires them. Phylogenetic trees represent our best estimates about evolutionary relationships, given our current knowledge. They are continually modified as additional evidence becomes available.

parsimony principle Preferring the simplest among a set of plausible explanations of any phenomenon.

Phylogenies are reconstructed from many sources of data

Naturalists have constructed various forms of phylogenetic trees for more than 150 years. In fact, the only figure in the first edition of *On the Origin of Species* was a phylogenetic tree. Tree construction has been revolutionized, however, by the advent of computer software that allows us to consider far more data and analyze far more traits than could ever before be processed. Combining these advances in methodology with the massive comparative data sets being generated through studies of genomes, biologists are learning details about the tree of life at a remarkable pace (see [Appendix A: The Tree of Life](#)).

Any trait that is genetically determined, and therefore heritable, can be used in a phylogenetic analysis. Evolutionary relationships can be revealed through studies of morphology, development, the fossil record, behavioral traits, and molecular traits such as DNA and protein sequences. Let's take a closer look at the types of data used in modern phylogenetic analyses.

MORPHOLOGY

An important source of phylogenetic information is **morphology**: the presence, size, shape, and other attributes of body parts. Since living organisms have been observed, depicted, collected, and studied for millennia, we have a wealth of recorded morphological data as well as extensive museum and herbarium collections of organisms whose traits can be measured. New technological tools, such as the electron microscope and computed tomography (CT) scans, enable systematists to examine and analyze the structures of organisms at much finer scales than was formerly possible.

morphology (more fol' o jee) [Gk. *morphe*: form + *logos*: study, discourse] The scientific study of organic form, including both its development and function.

Most species are described and known primarily by their morphology, and morphology still provides the most comprehensive data set available for many taxa. The morphological features that are important for phylogenetic analysis are often specific to a particular group. For example, the presence, development, shape, and size of various features of the skeletal system are important in vertebrate phylogeny, whereas floral structures are important for studying the relationships among flowering plants.

Morphological approaches to phylogenetic analysis have some limitations, however. Some taxa exhibit little morphological diversity, despite great species diversity. For example, the phylogeny of the leopard frogs of North and Central America would be difficult to infer from morphological differences alone, because the many species look very similar, despite important differences in their behavior and physiology. At the other extreme, few morphological traits can be compared across distantly related species (earthworms and mammals, for example). Furthermore, some morphological variation has an environmental (rather than a genetic) basis and so must be excluded from phylogenetic analyses. An accurate phylogenetic analysis often requires information beyond that supplied by morphology.

DEVELOPMENT

Similarities in ***developmental patterns** may reveal evolutionary relationships. Some organisms exhibit similarities only in early developmental stages. The larvae of marine creatures called sea squirts, for example, have a flexible gelatinous rod in the back—the notochord—that disappears as the larvae develop into adults. All vertebrate animals also have a notochord at some time during their development ([Figure 21.6](#)). This shared structure is one of the reasons for inferring that sea squirts are more closely related to vertebrates than would be suspected if only adult sea squirts were examined.

Sea squirt larva

Sea squirt and frog larvae (tadpoles) share several morphological similarities, including the presence of a notochord for body support.

Frog larva

Adult

Adult

Despite the similarity of their larvae, the **morphology** of adult frogs and sea squirts provides little evidence of the common ancestry of these two groups.

Figure 21.6 Development Reveals the Evolutionary Relationship between Sea Squirts and Vertebrates All chordates—a taxonomic group that includes sea squirts and frogs — have a notochord at some stage of their development. The larvae share similarities that are not apparent in the adults. Such similarities in development can provide useful evidence of evolutionary relationships. The notochord is lost in adult sea squirts. In adult frogs, as in all vertebrates, the vertebral column replaces the notochord as the support structure.

PALEONTOLOGY

The fossil record is another important source of information on evolutionary history. Fossils show us where and when organisms lived in the past and give us an idea of what they looked like. Fossils provide important evidence that helps us distinguish ancestral from derived traits. The fossil record can also reveal when lineages diverged and began their independent evolutionary histories. Furthermore, in groups with few species that have survived to the present, information on extinct species is often critical to an understanding of the large divergences among the surviving species. The fossil record has limitations, however. Few or no fossils have been found for some groups, and the fossil record for many groups is fragmentary.

BEHAVIOR

Some behavioral traits are culturally transmitted and others are genetically inherited. If a particular behavior is culturally transmitted, it may not accurately reflect evolutionary relationships (but may nonetheless reflect cultural connections). Many bird songs, for instance, are learned and may be inappropriate traits for phylogenetic analysis. Frog calls, however, are genetically determined and appear to be acceptable sources of information for reconstructing phylogenies.

MOLECULAR DATA

All heritable variation is encoded in DNA, and so the complete genome of an organism contains an enormous set of traits (the individual nucleotide bases of DNA) that can be used in phylogenetic analyses. In recent years, DNA sequences have become among the most widely used sources of data for constructing phylogenetic trees. Comparisons of nucleotide sequences are not limited to the DNA in the cell nucleus. Eukaryotes have genes in their mitochondria as well as in their nuclei. Plant cells also have genes in their chloroplasts. The chloroplast genome (cpDNA), which is used extensively in phylogenetic studies of plants, has changed slowly over evolutionary time, so it is often used to study relatively ancient phylogenetic relationships. Most animal mitochondrial DNA (mtDNA) has changed more rapidly, so mitochondrial genes are used to study evolutionary relationships among closely related animal species (the mitochondrial genes of plants evolve more slowly). Many nuclear gene sequences are also commonly analyzed, and now that entire genomes have been sequenced from many species, they too are used to construct phylogenetic trees. Information on gene products (such as the amino acid sequences of proteins) is also widely used for phylogenetic analyses.

Mathematical models expand the power of phylogenetic reconstruction

As biologists began to use DNA sequences to infer phylogenies in the 1970s and 1980s, they developed explicit mathematical models describing how DNA sequences change over time. These models account for multiple changes at a given position in a DNA sequence. They also take into account different rates of change at different positions in a gene, at different positions in a codon, and among different nucleotides. For example, transitions (changes between two purines or between two pyrimidines) are usually more likely than are transversions (changes between a purine and pyrimidine).

Mathematical models can be used to compute how a tree might evolve given the observed data. A [maximum likelihood](#) method will identify the tree that most likely produced the observed data, given the assumed model of evolutionary change. Maximum likelihood methods can be used for any kind of characters, but they are most often used with molecular data, for which explicit mathematical models of evolutionary change are easier to develop. The principal advantages of maximum likelihood analyses are that they incorporate more information about evolutionary change than do parsimony methods, and they are easier to treat in a statistical framework. The principal disadvantages are that they are computationally intensive and require explicit models of evolutionary change (which may not be available for some kinds of character change).

maximum likelihood A statistical method of determining which of two or more hypotheses (such as phylogenetic trees) best fit the observed data, given an explicit model of how the data were generated.

The accuracy of phylogenetic methods can be tested

If phylogenetic trees represent reconstructions of past events, and if many of these events occurred before any humans were around to witness them, how can we test the accuracy of phylogenetic methods? Biologists have conducted experiments both in living organisms and with

computer simulations that have demonstrated the effectiveness and accuracy of phylogenetic methods.

In one experiment designed to test the accuracy of phylogenetic analysis, a single viral culture of bacteriophage T7 was used as a starting point, and lineages were allowed to evolve from this ancestral virus in the laboratory (**Investigating Life: Testing the Accuracy of Phylogenetic Analysis**). The initial culture was split into two separate lineages, one of which became the ingroup for analysis and the other of which became the outgroup for rooting the tree. The lineages in the ingroup were split in two after every 400 generations, and samples of the virus were saved for analysis at each branching point. The lineages were allowed to evolve until there were eight lineages in the ingroup. Mutagens were added to the viral cultures to increase the mutation rate so that the amount of change and the degree of homoplasy would be typical of the organisms analyzed in average phylogenetic analyses. The investigators then sequenced samples from the end points of the eight ingroups and one outgroup lineages, as well as from the ancestors at the branching points. They then gave the sequences from the end points of the lineages to other investigators to analyze, without revealing the known history of the lineages or the sequences of the ancestral viruses.

After the phylogenetic analysis was completed, the investigators asked two questions. Did phylogenetic methods reconstruct the known history correctly? And were the sequences of the ancestral viruses reconstructed accurately? The answer in both cases was yes. The branching order of the lineages was reconstructed exactly as it had occurred, more than 98 percent of the nucleotide positions of the ancestral viruses were reconstructed correctly, and 100 percent of the amino acid changes in the viral proteins were reconstructed correctly.

The experiment shown in **Investigating Life: Testing the Accuracy of Phylogenetic Analysis** demonstrated that phylogenetic analysis was accurate under the conditions tested, but it did not examine all possible conditions. Other experimental studies have taken other factors into account, such as the sensitivity of phylogenetic analysis to convergent environments and highly variable rates of evolutionary change. In addition, computer simulations based on evolutionary models have been used extensively to study the effectiveness of phylogenetic analysis. These studies have also confirmed the accuracy of phylogenetic methods and have been used to refine those methods and extend them to new applications.

investigatinglife Testing the Accuracy of Phylogenetic Analysis

experiment

Original Paper: Hillis, D. M., J. J. Bull, M. E. White, M. R. Badgett, and I. J. Molineux. 1992. Experimental phylogenetics: Generation of a known phylogeny. *Science* 255: 589–592.

To test whether analysis of gene sequences can accurately reconstruct evolutionary phylogeny, we must have an unambiguously known phylogeny to compare against the reconstruction. Will the observed phylogeny match the reconstruction?

HYPOTHESIS▶ A phylogeny reconstructed by analyzing the DNA sequences of living organisms can accurately match the known evolutionary history of the organisms.

METHOD In the laboratory, researchers produced an unambiguous phylogeny of nine viral lineages, enhancing the mutation rate to increase variation among the lineages.

Viral sequences from the end points of each lineage (blue dots) were subjected to phylogenetic analysis by investigators who were unaware of the history of the lineages or the gene sequences of the ancestral viruses. These investigators reconstructed the phylogeny and ancestral DNA sequences based solely on their analyses of the descendants' genomes.

RESULTS The true phylogeny and ancestral DNA sequences were accurately reconstructed solely from the DNA sequences of the viruses at the tips of the tree branches.

CONCLUSION▶ Phylogenetic analysis of DNA sequences can accurately reconstruct evolutionary history.

1 Select single viral plaque (source of common ancestor).

2 Split each lineage every 400 generations, sequencing each ancestor at time of split.

work with the data

Original Paper: Bull, J. J., C. W. Cunningham, I. J. Molineux, M. R. Badgett, and D. M. Hillis. 1993. Experimental molecular evolution of bacteriophage T7. *Evolution* 47: 993–1007.

The full DNA sequences for the viral lineages produced in this experiment are thousands of nucleotides long. However, 23 of the nucleotide positions are shown in the table below, and you can use these data to repeat the researchers' analysis. Each nucleotide position represents a separate character.

QUESTIONS

1. Construct a phylogenetic tree from the nucleotide positions using the parsimony principle (see Key Concept 21.2 and the examples in Table

21.1 and Figure 21.5). Use the outgroup to root your tree. Assume that all changes among nucleotides are equally likely.

2. Using your tree from Question 1, reconstruct the DNA sequences of the ancestral lineages.
3. Transitions are mutations that change one purine to the other ($G \leftrightarrow A$) or one pyrimidine to the other ($C \leftrightarrow T$), whereas transversions exchange a purine for a pyrimidine or vice versa (e.g., $A \rightarrow C$ or T ; $C \rightarrow A$ or G). Which kind of mutation predominates in this phylogeny? Why might this be the case?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Animation 21.1 Using Phylogenetic Analysis to Reconstruct Evolutionary History

www.Life11e.com/a21.1

21.2 recap

Phylogenetic trees can be constructed by using the parsimony principle to find the simplest explanation for phylogenetic data. Maximum likelihood methods incorporate more explicit

mathematical models of evolutionary change to reconstruct evolutionary history.

learning outcomes

You should be able to:

- Analyze a phylogenetic tree to identify synapomorphies, homoplasies, and relationships among taxa. Draw and label the parts of a phylogenetic tree and explain the biological interpretation of each part.
- Reconstruct a phylogenetic tree from a data matrix of characters.

The matrix at right supplies data for seven land plants and an outgroup: an aquatic plant known as a stonewort. Each trait is scored as either present (+) or absent (-) in each of the plants. Use this data matrix to reconstruct the phylogeny of land plants and answer the questions that follow.

Taxon	Trait						
	Protected embryos	True roots	Persistently green sporophyte	Vascular cells	Stomata	Megaphylls (true leaves)	Seeds
Stonewort (outgroup)	-	-	-	-	-	-	-
Liverwort	+	-	-	-	-	-	-
Pine tree	+	+	+	+	+	+	+
Bracken fern	+	+	+	+	+	+	-
Club moss	+	+	+	+	+	-	-
Sphagnum moss	+	-	-	-	+	-	-
Hornwort	+	-	+	-	+	-	-
Sunflower	+	+	+	+	+	+	+

1. Which two of these taxa are most closely related?
2. Plants that produce seeds are known as seed plants. What is the sister group to the seed plants among these taxa?
3. Which two traits evolved along the same branch of your reconstructed phylogeny?
4. Are there any homoplasies in your reconstructed phylogeny?

Why do biologists expend the time and effort necessary to reconstruct phylogenies? Information about the evolutionary relationships among organisms is a useful source of data for scientists investigating a wide variety of biological questions. Next we will describe how phylogenetic trees are used to answer questions about the past, and to predict and compare traits of organisms in the present.

***connect the concepts** Evolutionary developmental biology, the subject of [Chapter 19](#), compares the developmental processes of different organisms to determine the ancestral relationship between them, and to discover how developmental processes evolved. Genetic toolkit genes are expressed in different ways in different species, resulting in major morphological differences among species (see [Key Concepts 19.4](#) and [19.5](#)). The existence of

highly conserved development genes makes it likely that similar traits will evolve repeatedly.

21.3 Phylogeny Makes Biology Comparative and Predictive

Once a phylogeny is reconstructed, what do we do with it? What beyond an understanding of evolutionary history does phylogeny offer us?

focus your learning

Biologists use phylogenetic trees to investigate living organisms, explore instances of convergent evolution, and reconstruct ancestral states.

The timing of an evolutionary event can be estimated using the average rate of change for a given gene or protein and known calibration dates.

Phylogenetic trees can be used to reconstruct past events

Reconstructing past events is important for understanding many biological processes. In the case of zoonotic diseases (diseases caused by infectious organisms transmitted to humans from another animal host), it is important to understand when, where, and how the disease first entered a human population. Human immunodeficiency virus (HIV) is the cause of such a zoonotic disease, acquired immunodeficiency syndrome, or AIDS. Phylogenetic analyses have become important for studying the transmission of viruses such as HIV. Phylogenies are also important for understanding the present global diversity of HIV and for determining the virus's origins in human populations. A broader phylogenetic analysis of immunodeficiency viruses shows that humans acquired these viruses from two different hosts: HIV-1 from chimpanzees, and HIV-2 from sooty mangabeys ([Figure 21.7](#)).

Figure 21.7 Phylogenetic Tree of Immunodeficiency Viruses The evolutionary

relationships of immunodeficiency viruses show that these viruses have been transmitted to humans from two different simian hosts: HIV-1 from chimpanzees and HIV-2 from sooty mangabeys. (SIV stands for simian immunodeficiency virus.)

HIV-1 is the common form of the virus in human populations in central Africa, where chimpanzees are hunted for food, and HIV-2 is the common form in human populations in western Africa, where sooty mangabeys are hunted for food. Thus it seems likely that these viruses entered human populations through hunters who cut themselves while skinning chimpanzees and sooty mangabeys. The global pandemic of AIDS occurred when these infections in local African populations rapidly spread through human populations around the world.

In recent years, phylogenetic analysis has become important in forensic investigations that involve viral transmission events. For example, phylogenetic analysis was critical for a criminal investigation of a physician who was accused of purposefully injecting blood from one of his HIV-positive patients into his former girlfriend in an attempt to kill her. The phylogenetic analysis revealed that the HIV strains present in the girlfriend were a subset of those present in the physician's patient ([Figure 21.8](#)). Other evidence was needed, of course, to connect the physician to this purposeful transmission event, but the phylogenetic analysis was important to support the viral transmission event from the patient to the victim.

Figure 21.8 A Forensic Application of Phylogenetic Analysis This phylogenetic analysis demonstrated that strains of HIV present in a victim (shown in red) were a phylogenetic subset of viruses isolated from a physician's patient (shown in blue). This analysis was part of the evidence used to show that the physician drew blood from his HIV-positive patient and injected it into the victim in an attempt to kill her. A jury found the physician guilty of attempted murder.

Q: What hypothetical phylogenetic results could have exonerated the physician?

Phylogenies allow us to compare and contrast living organisms

Male swordtails—a group of fish in the genus *Xiphophorus*—have a long, colorful tail extension, and their reproductive success is closely associated with this appendage. Males with a long sword are more likely to mate successfully than are males with a short sword (an example of sexual selection; see [Key Concept 20.2](#)). Several explanations have been advanced for the evolution of this structure, including the hypothesis that the sword simply exploits a preexisting bias in the sensory system of the females. This sensory exploitation hypothesis suggests that female swordtails had a preference for males with long tails even before the tails evolved (perhaps because females assess the size of males by their total body length—including the tail—and prefer larger males).

To test the sensory exploitation hypothesis, phylogenetic analysis was used to identify the relatives of swordtails that had split most recently from their lineage before the evolution of swords. These closest relatives turned out to be fish in the genus *Priapella*. Even though male *Priapella* do not normally have swords, when researchers attached artificial swordlike structures to the tails of male *Priapella*, female *Priapella* preferred those males. This result provided support for the hypothesis that female *Xiphophorus* had a preexisting sensory bias favoring tail extensions even before the trait evolved ([Figure 21.9](#)). Thus a long tail became a sexually selected trait because of the preexisting preference of the females. The phylogeny allows us to understand when the trait evolved relative to the change in female preference.

Figure 21.9 The Origin of a Sexually Selected Trait The tail extension of male swordtails (genus *Xiphophorus*) apparently evolved through sexual selection, as females mated preferentially with males that had long “swords.” Phylogenetic analysis reveals that *Priapella* split from the swordtails before the evolution of the sword. The independent finding that female *Priapella* prefer male *Priapella* with an artificial sword

further supports the idea that this appendage evolved as a result of a preexisting preference in females.

Phylogenies can reveal convergent evolution

Like most animals, flowering plants (angiosperms) often reproduce by mating with another individual of the same species. But in many angiosperm species, the same individual produces both male and female gametes (contained within pollen and ovules, respectively).

***Self-incompatible** species have mechanisms to prevent fertilization of the ovule by the individual's own pollen, and so must reproduce by outcrossing with another individual. Individuals of some species, however, regularly fertilize their ovules using their own pollen; they are self-fertilizing or selfing species, and their gametes are self-compatible.

The evolution of angiosperm fertilization mechanisms was examined in *Leptosiphon*, a genus in the phlox family that exhibits a diversity of mating systems and pollination mechanisms. The self-incompatible (outcrossing) species of *Leptosiphon* have long petals and are pollinated by long-tongued flies. In contrast, self-pollinating species have short petals and do not require insect pollinators to reproduce successfully. Using ribosomal DNA sequences, investigators reconstructed a phylogeny of this genus ([Figure 21.10](#)). They then determined whether each species was self-compatible by artificially pollinating flowers with the plant's own pollen or with pollen from other individuals and observing whether viable seeds formed.

L. bicolor (selfing)

L. liniflorus (outcrossing)

Figure 21.10 Phylogeny Reveals Convergent Evolution Self-compatibility apparently evolved independently three times among these species of the plant genus *Leptosiphon*. Because the appearance and structure of the flowers converged in the three selfing lineages, taxonomists mistakenly thought they were varieties of the same species.

The reconstructed phylogeny suggests that self-incompatibility is the ancestral state and that self-compatibility evolved three times within this group of *Leptosiphon*. The change to self-compatibility eliminated the plants' dependence on an outside pollinator and has been accompanied by the evolution of reduced petal size. Indeed, the striking morphological similarity of the flowers in the self-compatible groups once led to their being classified as members of a single species (*L. bicolor*). Phylogenetic analysis, however, shows them to be members of three distinct lineages. From this information we can infer that self-compatibility and its associated floral structure are convergent in the three independent lineages that had been called *L. bicolor*.

Ancestral states can be reconstructed

In addition to using phylogenetic methods to infer evolutionary relationships, biologists can use these techniques to reconstruct the morphology, behavior, or nucleotide and amino acid sequences of ancestral species (as was demonstrated for the ancestral sequence of bacteriophage T7 in Investigating Life: Testing the Accuracy of Phylogenetic Analysis). In the opening of this chapter, we described how Mikhail Matz used phylogenetic analysis to reconstruct the sequence of changes in fluorescent proteins of corals to understand how red fluorescent proteins could be produced.

Reconstruction of ancient DNA sequences can also provide information about the biology of long-extinct organisms. For example, phylogenetic analysis was used to reconstruct an opsin protein in the ancestral archosaur (the most recent common ancestor of birds, dinosaurs, and crocodiles). Opsins are pigment proteins involved in vision; different opsins (with different amino acid sequences) are excited by different wavelengths of light. Knowledge of the opsin sequence in the ancestral archosaur would provide clues about the animal's visual capabilities and therefore about some of its probable behaviors. Investigators used phylogenetic analysis of opsin from living vertebrates to estimate the amino acid sequence of the pigment that existed in the ancestral archosaur. A protein with this same sequence was then constructed in the laboratory. The investigators tested the reconstructed opsin and found a significant shift toward the red end of the spectrum in the light sensitivity of this protein compared with that of most modern opsins. Modern species that exhibit similar sensitivity are adapted for nocturnal vision, so the investigators inferred that the ancestral archosaur might have been active at night. Thus, reminiscent of the movies *Jurassic Park* and *Jurassic World*, phylogenetic analyses are being used to reconstruct extinct species, one protein at a time.

Molecular clocks help date evolutionary events

For many applications, biologists want to know not only the order in which evolutionary lineages split but also the timing of those splits. In 1965, Emile Zuckerkandl and Linus Pauling

hypothesized that rates of molecular change were constant enough that they could be used to predict evolutionary divergence times—an idea that has become known as the [molecular clock](#) hypothesis.

molecular clock The approximately constant rate of divergence of macromolecules from one another over evolutionary time; used to date past events in evolutionary history.

Of course, different genes evolve at different rates, and there are also differences in evolutionary rates among species related to differing generation times, environments, efficiencies of DNA repair systems, and other biological factors. Nonetheless, among closely related species, a given gene usually evolves at a reasonably constant rate. Therefore the protein encoded by the gene accumulates amino acid replacements at a relatively constant rate ([Figure 21.11](#)). A molecular clock uses the average rate at which a given gene or protein accumulates changes to gauge the time of divergence for a particular split in the phylogeny. Molecular clocks must be calibrated using independent data, such as the fossil record, known times of divergence, or biogeographic dates (e.g., the time of separations of continents). Using such calibrations, times of divergence have been estimated for many groups of species that have diverged over millions of years.

Figure 21.11 A Molecular Clock for the Protein Hemoglobin Amino acid replacements in hemoglobin have occurred at a relatively constant rate over nearly 500 million years of evolution. The graph shows the relationship between the time of divergence and the proportion of amino acids that have changed for 13 pairs of vertebrate hemoglobin proteins. The average rate of change represents the molecular clock for hemoglobin in vertebrates.

Molecular clocks are not only used to date ancient events; they are also used to study the timing of comparatively recent events. Most samples of HIV-1 have been collected from humans only since the early 1980s, although a few isolates from medical biopsies are available from as early as the 1950s. Biologists can use the observed changes in HIV-1 over the past several decades to project back to the common ancestor of all HIV-1 isolates, and estimate when HIV-1

first entered human populations from chimpanzees ([Figure 21.12](#)). This molecular clock was calibrated using the samples from the 1980s and 1990s, and then tested using the samples from the 1950s. As shown in [Figure 21.12C](#), a sample from a 1959 biopsy is dated by molecular clock analysis at 1957 ± 10 years. Extrapolation back to the common ancestor of the samples suggested a date of origin for this group of viruses of about 1930. Although AIDS was unknown to Western medicine until the 1980s, this analysis shows that HIV-1 was present (probably at a very low frequency) in human populations in Africa for at least a half-century before its emergence as a global pandemic. Biologists have used similar analyses to conclude that immunodeficiency viruses have been transmitted repeatedly into human populations from multiple primates for more than a century (see also [Figure 21.7](#)).

Figure 21.12 Dating the Origin of HIV-1 in Human Populations (A) A phylogenetic tree for samples of the main group of HIV-1 virus. The dates indicate the years in which the samples were taken. (For clarity, only a small fraction of the samples that were examined in the original study are shown.) (B) A plot of sample year versus genetic divergence from the common ancestor provided an average rate of divergence, or a molecular clock. (C) The molecular clock was used to date a sample taken in 1959 (as a test of the clock) and to estimate the date of origin of the HIV-1 main group (about 1930). Branch length from a common ancestor represents the average number of substitutions per nucleotide.

Q: What would be the expected branch length from the common ancestor of an HIV isolate from 1970?

21.3 recap

Phylogenetic trees are used to reconstruct the evolutionary history of lineages, to determine when and where traits arose, and to make biological comparisons among genes, populations, and species. They can also be used to reconstruct ancestral traits and to estimate the timing of evolutionary events.

learning outcomes

You should be able to:

- Use a phylogenetic tree to formulate a hypothesis about the origins of an epidemic.
- Calculate the rate of a molecular clock from a graph that shows change over time.

1. West Nile virus kills birds of many species and can cause fatal encephalitis (inflammation of the brain) in humans and horses. In the 1930s the virus was first isolated in Africa, where it is thought to be endemic. By the 1990s it had been found throughout much of Eurasia. West Nile virus was not found in North America until 1999, when it was first detected in New York, but since that time it has spread rapidly across most of the United States. Use the phylogenetic tree of West Nile virus isolates shown at right to construct a hypothesis about the origin of the virus lineage that was introduced into the United States. The isolates are identified by their place and date of isolation.

2. Researchers examined the molecular divergence of a mitochondrial DNA gene (*cyt b*) among sister species of birds called honeycreepers on different Hawaiian Islands. They then plotted the measured molecular divergence against the estimated dates for separation of the islands (see below). Calculate the average rate of change in *cyt b* (the molecular clock) from the graph.

All of life is connected through evolutionary history, and the relationships among organisms provide a natural basis for making biological comparisons. For these reasons, biologists use phylogenetic relationships as the basis for organizing life into a coherent classification system.

***connect the concepts** Some mechanisms of self incompatibility are discussed in [Key Concept 37.1](#).

21.4 Phylogeny Is the Basis of Biological Classification

The biological classification system in widespread use today is derived from a system developed by the Swedish biologist Carolus Linnaeus in the mid-1700s. Linnaeus developed a naming system called **binomial nomenclature** that has allowed scientists throughout the world to refer unambiguously to the same organisms by the same names.

binomial nomenclature [Gk. two names] A taxonomic naming system in which each species is given a binomial, a genus name followed by a species name.

focus your learning

Only monophyletic groups are considered appropriate taxonomic units.

Classifications are used to organize and name groups on the tree of life.

Linnaeus gave each species a two-part name, one part identifying the species itself and the other the genus to which it belongs. A **genus** (plural *genera*) is a group of closely related species. Optionally, the name of the taxonomist who first proposed the species name may be added at the end. Thus *Homo sapiens* Linnaeus is the name of the modern human species. *Homo* is the genus to which the species belongs, and *sapiens* identifies the particular species in the genus *Homo*; Linnaeus proposed the species name *Homo sapiens*.

genus (jean' us) (plural: genera) [Gk. *genos*: stock, kind] A group of related, similar species recognized by taxonomists with a distinct name used in binomial nomenclature.

You can think of *Homo* as equivalent to your surname and *sapiens* as equivalent to your first name. The first letter of the genus name is capitalized, and the specific name is lowercase. Both of these formal designations are italicized. Rather than repeating the name of a genus when it is used several times in the same discussion, biologists often spell it out only once and abbreviate it to the initial letter thereafter (e.g., *D. melanogaster* rather than *Drosophila melanogaster*).

As we noted earlier, any group of organisms that is treated as a unit in a biological classification system, such as all species in the genus *Drosophila*, or all insects, or all arthropods, is called a taxon. In the Linnaean system, species and genera are further grouped into a hierarchical system of higher taxonomic categories. The taxon above the genus in the Linnaean system is the family. The names of animal families end in the suffix “-idae.” Thus Formicidae is the family that contains all ant species, and the family Hominidae contains humans and our recent fossil relatives, as well as our closest living relatives, the chimpanzees and gorillas. Family names are based on the name of a member genus; Formicidae is based on the genus *Formica*, and Hominidae is based on *Homo*. The same rules are used in classifying plants, except that the suffix “-aceae” is used for plant family names instead of “-idae.” Thus Rosaceae is the family that includes the genus *Rosa* (roses) and its relatives.

In the Linnaean system, families are grouped into orders, orders into classes, classes into phyla (singular *phylum*), and phyla into kingdoms. However, the ranking of taxa within Linnaean

classification is subjective. Whether a particular taxon is considered, say, an order or a class is informative only with respect to the *relative* ranking of other related taxa. Although families are always grouped within orders, orders within classes, and so forth, there is nothing that makes a “family” in one group equivalent (in number of genera or in evolutionary age, for instance) to a “family” in another group.

Linnaeus recognized the overarching hierarchy of life, but he developed his system before evolutionary thought had become widespread. Biologists today recognize the tree of life as the basis for biological classification and often name taxa without placing them into the various Linnaean ranks.

Evolutionary history is the basis for modern biological classification

Today’s biological classifications express the evolutionary relationships of organisms. Taxa are expected to be **monophyletic**, meaning that the taxon contains an ancestor and all descendants of that ancestor, and no other organisms. In other words, a monophyletic taxon is a historical group of related species, or a complete branch on the tree of life. As noted earlier, this is also the definition of a **clade**. A true monophyletic group can be removed from a phylogenetic tree by a single “cut” in the tree, as shown in [Figure 21.13](#).

monophyletic (mon’ oh fih leht’ ik) [Gk. *mono*: one + *phylon*: tribe] Pertaining to a group that consists of an ancestor and all of its descendants. (Contrast with paraphyletic, polyphyletic.)

Figure 21.13 Monophyletic, Polyphyletic, and Paraphyletic Groups Monophyletic groups are the basis of taxa in modern biological classifications. Polyphyletic and paraphyletic groups are not appropriate for use in classifications because they do not accurately reflect evolutionary history.

Note that there are many monophyletic groups on any phylogenetic tree, and that these groups are successively smaller subsets of larger monophyletic groups. This hierarchy of biological taxa, with all of life as the most inclusive taxon and many smaller taxa within larger taxa, down to the individual species, is the modern basis for biological classification.

Although biologists seek to describe and name only monophyletic taxa, the detailed phylogenetic information needed to do so is not always available. A group that does not include its common ancestor is **polyphyletic**. A group that does not include all the descendants of a common ancestor is referred to as **paraphyletic** (see [Figure 21.13](#)). Virtually all taxonomists now agree that polyphyletic and paraphyletic groups are inappropriate as taxonomic units because they do not correctly reflect evolutionary history. Some classifications still contain such groups because some organisms have not been evaluated phylogenetically. As mistakes in prior classifications are detected, taxonomic names are revised and polyphyletic and paraphyletic groups are eliminated from the classifications.

polyphyletic (pol' lee fih leht' ik) [Gk. *poly*: many + *phylon*: tribe] Pertaining to a group that consists of multiple distantly related organisms, and does not include the common ancestor of the group. (Contrast with monophyletic, paraphyletic.)

paraphyletic (par' a fih leht' ik) [Gk. *para*: beside + *phylon*: tribe] Pertaining to a group that consists of an ancestor and some, but not all, of its descendants. (Contrast with monophyletic, polyphyletic.)

Several codes of biological nomenclature govern the use of scientific names

Several sets of explicit rules govern the use of scientific names. Biologists around the world follow these rules voluntarily to facilitate communication and dialogue. There may be dozens of common names for an organism in many different languages, and the same common name may refer to more than one species ([Figure 21.14](#)). The rules of biological nomenclature are designed so that there is only one correct scientific name for any single recognized taxon, and (ideally) a given scientific name applies only to a single taxon (that is, each scientific name is unique). Sometimes the same species is named more than once (when more than one taxonomist has taken up the task). In these cases, the rules specify that the valid name is the first name that was proposed. If the same name is inadvertently given to two different species, then the species that was named second must be given a new name.

(A) *Asclepias tuberosa*

(B) *Castilleja coccinea*

(C) *Hieracium aurantiacum*

Figure 21.14 Same Common Name, Not the Same Species All three of these distinct plant species are called “Indian paintbrush.” Binomial nomenclature allows us to avoid the ambiguity of such common names and communicate exactly what is being described. (A) *Asclepias tuberosa* is a perennial milkweed native to eastern North America. (B) *Castilleja coccinea* is also native to eastern North America, but is a member of a very different group of plants called scrophs. (C) *Hieracium aurantiacum* is a European species of aster that has been widely introduced into North America.

Because of the historical separation of the fields of zoology, botany (which originally included mycology, the study of fungi), and microbiology, different sets of taxonomic rules were developed for each of these groups. Yet another set of rules emerged later for classifying viruses. This separation of fields resulted in duplicated taxon names in groups governed by the different sets of rules. *Drosophila*, for example, is both a genus of fruit flies and a genus of fungi, and some species in both groups have identical names. Until recently these duplicated names caused little confusion, since traditionally biologists who studied fruit flies were unlikely to read the literature on fungi (and vice versa). Today, given the prevalence of large, universal biological databases (such as GenBank, which includes DNA sequences from across all life), it is increasingly important that each taxon have a unique and unambiguous name. Biologists are working on a universal code of nomenclature that can be applied to all organisms, so that every species will have a unique identifying name or registration number. This will assist efforts to build an online *Encyclopedia of Life* that links all the information for all the world’s species.

21.4 recap

Biologists organize and classify life by identifying and naming monophyletic groups. Several sets of rules govern the use of scientific names so that each species and higher taxon can

be identified and named unambiguously.

learning outcomes

You should be able to:

- Use a phylogeny to build a classification for a group of organisms.
- Analyze a classification and phylogenetic tree to identify monophyletic, polyphyletic, and paraphyletic groups.

Consider the phylogeny and three possible classifications shown below.

1. Which of these classifications contain a paraphyletic group?
2. Which of these classifications contains a polyphyletic group?
3. Which of these classifications is consistent with the goal of including only monophyletic groups in a biological classification?

Classification one:

Named group

Amphibia
Mammalia
Reptilia
Aves

Included taxa

Frogs, salamanders, and caecilians
Mammals
Lizards, turtles, and crocodiles
Birds

Classification two:

Named group

Amphibia
Mammalia
Reptilia

Included taxa

Frogs, salamanders, and caecilians
Mammals
Lizards, turtles, crocodiles, and birds

Classification three:

Named group

Amphibia
Homothermia

Included taxa

Frogs, salamanders, and caecilians
Mammals and birds

Now that we have seen how evolution occurs and how phylogenies can be used to study evolutionary relationships, we are ready to consider the process of speciation. Speciation is what leads to the branching events on the tree of life, and it is the process that results in the millions of species that constitute biodiversity.

▶ investigatinglife

QA How are phylogenetic methods used to resurrect protein sequences from extinct organisms?

Most genes and proteins of organisms that lived millions of years ago have decomposed in the fossil remains of these species. Nonetheless, the sequences of many ancient genes and proteins can be reconstructed by the methods described in this chapter. As we saw in *Investigating Life: Testing the Accuracy of Phylogenetic Analysis*, we can reconstruct ancestral DNA sequences—if we have enough information about the genomes of their descendants. Biologists have reconstructed gene sequences from species that have been extinct for millions of years. Using this information, a laboratory can reconstruct real proteins that correspond to those gene sequences. This is how Mikhail Matz and his colleagues were able to resurrect fluorescent proteins from the extinct ancestors of modern corals, then visualize the colors produced by these proteins in the laboratory ([Figure 21.15](#)).

Figure 21.15 Evolution of Fluorescent Proteins of Corals Mikhail Matz and his colleagues used phylogenetic analysis to reconstruct the sequences of fluorescent proteins that were present in the extinct ancestors of modern corals. They then expressed these proteins in bacteria and plated the bacteria in the form of a phylogenetic tree to show how the colors evolved over time.

Future directions

Biologists are now using phylogenetic analysis to reconstruct many ancient protein sequences. These reconstructed protein sequences are then made into actual proteins in the laboratory. For example, when biologists measured the temperature optima for resurrected proteins that were present in the

common ancestor of all life, they found that the proteins functioned best in the range of 55°C-65°C. This result is consistent with hypotheses that life evolved in a high- temperature environment.

To reconstruct protein sequences from species that have been extinct for millions or even billions of years, biologists use detailed mathematical models that take into account much of what we have learned about molecular evolution, as described in [Key Concept 21.2](#). These models incorporate information on rates of replacement among different amino acids in proteins, information on different substitution rates among nucleotides, and changes in the rate of molecular evolution among the major lineages of life. These studies are opening up opportunities to see how proteins have evolved through time and how extinct species once functioned.

► 21.1 All of Life Is Connected through Its Evolutionary History

- **Phylogeny** is the history of evolutionary relationships among organisms or their genes. Groups of evolutionarily related species are represented as branches in a **phylogenetic tree**. **Review Figures 21.1, Focus: Key Figure 21.2**

phylogeny (fy loj' e nee) [Gk. *phylon*: tribe, race + *genesis*: source] The evolutionary history of a particular group of organisms or their genes.

phylogenetic tree A graphic representation of these lines of evolutionary descent.

- Named species and groups of species are called **taxa**. A taxon that consists of an ancestor and all of its evolutionary descendants is called a **clade**. **Review Figure 21.3**

clade [Gk. *klados*: branch] A monophyletic group made up of an ancestor and all of its descendants.

- **Homologies** are similar traits that have been inherited from a common ancestor. **Review Figure 21.4**

homolog (1) In cytogenetics, one of a pair (or larger set) of chromosomes having the same overall genetic composition and sequence. In diploid organisms, each chromosome inherited from one parent is matched by an identical (except for mutational changes) chromosome—its homolog—from the other parent. (2) In evolutionary biology, one of two or more features in different species that are similar by reason of descent from a common ancestor.

- A derived trait that is shared by two or more taxa and is inherited from their common ancestor is called a **synapomorphy**.

synapomorphy A trait that arose in the ancestor of a phylogenetic group and is present (sometimes in modified form) in all of its members, thus helping to delimit and identify that group. Also called a shared derived trait. (Contrast with derived trait.)

- Distantly related species may show similar traits that do not result from common ancestry. **Convergent evolution** and **evolutionary reversals** can give rise to such traits, which are called **homoplasies**.

convergent evolution Independent evolution of similar features from different ancestral traits.
evolution Any gradual change. Most often refers to organic or Darwinian evolution, which is the genetic and resulting phenotypic change in populations of organisms from generation to generation. (See macroevolution, microevolution. Contrast with speciation.)

► 21.2 Phylogeny Can Be Reconstructed from Traits of Organisms

- Phylogenetic trees can be constructed from synapomorphies using the logic of **parsimony**. **Review Figure 21.5, Activities 21.1, 21.2**
- Sources of phylogenetic information include **morphology**, patterns of development, the fossil record, behavioral traits, and molecular traits such as DNA and protein sequences.

morphology (more fol' o jee) [Gk. *morphe*: form + *logos*: study, discourse] The scientific study of organic form, including both its development and function.

- Phylogenetic trees can also be constructed with **maximum likelihood** methods, which find the tree most likely to have generated the observed data under a specific model of evolution.

maximum likelihood A statistical method of determining which of two or more hypotheses (such as phylogenetic trees) best fit the observed data, given an explicit model of how the data were generated.

- Phylogenetic methods have been tested in both experimental and simulation studies, and have been shown to be accurate under a wide variety of conditions. **See Animation 21.1**

► 21.3 Phylogeny Makes Biology Comparative and Predictive

- Phylogenetic trees are used to make comparisons among living organisms. **Review Figure 21.9**
- Phylogenetic trees are used to reconstruct the past and to understand the origin of traits. **Review Figure 21.10**
- Biologists can use phylogenetic trees to reconstruct ancestral states.
- Phylogenetic trees may include estimates of divergence times of lineages determined by **molecular clock** analysis. **Review Figure 21.12**

molecular clock The approximately constant rate of divergence of macromolecules from one another over evolutionary time; used to date past events in evolutionary history.

► 21.4 Phylogeny Is the Basis of Biological Classification

- Biologists use phylogenetic relationships to organize life into a coherent classification system.
- Taxa in modern classifications are expected to be **monophyletic** groups. **Paraphyletic** and **polyphyletic** groups are not considered appropriate taxonomic units. **Review Figure 21.13, Activity 21.3**

monophyletic (mon' oh fih leht' ik) [Gk. *mono*: one + *phylon*: tribe] Pertaining to a group that consists of an ancestor and all of its descendants. (Contrast with paraphyletic, polyphyletic.)

paraphyletic (par' a fih leht' ik) [Gk. *para*: beside + *phylon*: tribe] Pertaining to a group that consists of an ancestor and some, but not all, of its descendants. (Contrast with monophyletic, polyphyletic.)

polyp (pah' lip) [Gk. *poly*: many + *pous*: foot] In cnidarians, a sessile, asexual life cycle stage.

- Several sets of rules govern the use of scientific names, with the goal of providing unique and universal names for taxa.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. LearningCurve adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

- 1.1 Phylogenetic trees represent evolutionary relationships.
 - 1.2 Phylogenies enable biologists to compare organisms and make predictions and inferences based on similarities and differences in traits.
 - 1.3 Biologists use phylogenetic trees to investigate living organisms, explore instances of convergent evolution, and reconstruct ancestral states.

Original Paper: Scaduto, D. I., J. M. Brown, W. C. Haaland, D. J. Zwickl, D. M. Hillis, and M. L. Metzker. 2010. Source identification in two criminal cases using phylogenetic analysis of HIV-1 DNA sequences. *Proceedings of the National Academy of Sciences USA* 107:21242-21247.

Phylogenetic trees are used throughout biology, but only in recent years have they become important for forensic investigations. In these cases, samples are “blinded” to the investigators by assigning numbers to each sample, rather than using people’s names. Only after the conclusions are finalized do other investigators decode the numbers to reveal the results.

A recent criminal case in Texas charged a defendant with knowingly and intentionally infecting a series of women with HIV. A phylogenetic analysis was used to demonstrate that the defendant transmitted HIV to his victims. (Other evidence was needed to prove knowledge and intent.) In this case, sequences of HIV isolated from the victims and the defendant, together with the closest sequences from an HIV database (the outgroup), were compared and used to construct a phylogenetic tree of the viruses. Viruses from each individual in the case are colored alike on the tree to the right. The labels are the codes for the individuals in the case. All of the individuals labeled CC01-CC08 are known to have engaged in sex; they represent an epidemiological cluster.

Questions

1. Which of the individuals labeled in the tree is consistent with being the source of this infection cluster? Why?
2. Why is the tree inconsistent with any of the other individuals being the source of infection within this cluster?
3. What was the purpose of including an outgroup made up of individuals that were outside the epidemiological cluster?

Speciation

This composite photograph shows a few of the nearly 1,000 species of haplochromine cichlids that are endemic to Lake Malawi, all of which are from a single founder species.

key concepts

- [2.1 Species Are Reproductively Isolated Lineages on the Tree of Life](#)
- [2.2 Speciation Is a Natural Consequence of Population Subdivision](#)
- [2.3 Speciation May Occur through Geographic Isolation or in Sympatry](#)
- [2.4 Reproductive Isolation Is Reinforced When Diverging Species Come into Contact](#)
- [2.5 Speciation Rates Are Highly Variable across Life](#)

Rapid Speciation in African Lake Cichlids

Not quite 2 million years ago, a tectonic split in the Great Rift Valley of East Africa led to the formation of Lake Malawi, which lies between the modern countries of Malawi, Tanzania, and Mozambique. A few fish species entered the new lake, including a type known as a haplochromine cichlid. Today the descendants of this early invader include nearly 1,000 species of haplochromine cichlids. All of them are endemic to Lake Malawi—they are found nowhere else. This vast array of cichlid species makes this the most diverse lake in the world in terms of its fish fauna. How did so many different species arise from a single ancestral species in less than 2 million years?

By studying the history and timing of speciation events in Lake Malawi, biologists have pieced together some of the processes that led to so many cichlid species. The earliest haplochromine cichlids to enter the new lake encountered diverse habitats in Lake Malawi, as some shores were rocky and others were sandy. Cichlid populations quickly adapted to these distinct habitat types. Fish in rocky habitats adapted to breeding and living in rocky conditions, and those in sandy habitats evolved specializations for life over sand. These changes resulted in an early speciation event.

Within each of these major habitat types, there were numerous opportunities for diet specialization. Various populations of cichlids became rock scrapers, bottom feeders, fish predators, scale biters, pelagic zooplankton eaters, or plant specialists. Each of these feeding specializations requires a different mouth morphology. The offspring of fish that bred with fish of similar morphology were more likely to survive than were fish with two very different parents. These differences in fitness led to the formation of many more new species, each adapted to a different feeding mode.

The Lake Malawi cichlids continued to diverge and form new species. Male cichlids compete for the attention of females through their bright body colors. Diversification of the body colors of males, and of the preferences of females for different body colors, led to many more new species of cichlids, each isolated from the other by its sexual preferences. Now biologists are studying the genomes of these Lake Malawi cichlids to understand the details of the genetic changes that have given rise to so many species over so little time.

QA If speciation typically takes thousands to millions of years, how do biologists conduct experiments to study this process?

22.1 Species Are Reproductively Isolated Lineages on the Tree of Life

Biological diversity does not vary in a smooth, continuous way. People have long recognized groups of similar organisms that mate with one another, and they have noticed that there are usually distinct morphological breaks between these groups. Groups of organisms that mate with one another are commonly called **species** (note that this is both the plural and singular form of the word). Species are the result of the process of **speciation**: the divergence of biological lineages and the emergence of reproductive isolation between lineages.

species (spee' sees) [L. kind] The base unit of taxonomic classification, consisting of an ancestor–descendant group of populations of evolutionarily closely related, similar organisms. The more narrowly defined “biological species” consists of individuals capable of interbreeding with each other but not with members of other species.

speciation (spee' see ay' shun) The process of splitting one population into two populations that are reproductively isolated from one another. (Contrast with evolution.)

focus your learning

Biologists approach the concept of species differently, depending on the focus of their research.

The various species concepts are connected by the importance of reproductive isolation in understanding the origin of species.

Although “species” is a useful and common term, its usage varies among biologists who are interested in different aspects of speciation. Different biologists think about species differently because they ask different questions: How can we recognize and identify species? How do new species arise? How do different species remain separate? Why do rates of speciation differ among groups of organisms? In answering these questions, biologists focus on different attributes of species, leading to several different ways of thinking about what species are and how they form. Most of the various **species concepts** proposed by biologists are simply different ways of approaching the question “What are species?” Let's compare three major classes of species concepts to contrast the way that biologists think about species.

species concepts The ways that biologists think about the category of species.

We can recognize many species by their appearance

Someone who is knowledgeable about a group of organisms, such as birds or flowering plants, can usually distinguish the different species found in a particular area simply by looking at them. Standard field guides to birds, mammals, insects, and wildflowers are possible only because many species change little in appearance over large geographic distances (**Figure 22.1A**).

(A)

Lophodytes cucullatus
Male, British Columbia

Lophodytes cucullatus
Male, New Mexico

(B)

Lophodytes cucullatus
Female

Figure 22.1 Not All Members of the Same Species Look Alike (A) It is easy to identify these two male hooded mergansers as members of the same species, even though they were photographed thousands of miles apart in British Columbia and New Mexico, respectively. Despite their geographic separation, the two individuals are morphologically very similar. (B) Hooded mergansers are sexually dimorphic, which means the female's appearance is quite different from that of the male.

More than 250 years ago, Carolus Linnaeus developed the system of binomial nomenclature

by which species are named today (see [Key Concept 21.4](#)). Linnaeus described and named thousands of species, but because he knew nothing about the genetics or the mating behavior of the organisms he was naming, he classified them on the basis of their appearance alone. In other words, Linnaeus used a [morphological species concept](#), a construct that assumes that a species comprises individuals that “look alike” and that individuals that do not look alike belong to different species. Although Linnaeus could not have known it, the members of most of the groups he classified as species look alike because they share many alleles of the genes that code for their morphological features.

morphological species concept The definition of a species as a group of individuals that look alike. (Contrast with biological species concept, lineage species concept.)

Using morphology to define species has limitations. Members of the same species do not always look alike. For example, males, females, and young individuals do not always resemble one another closely ([Figure 22.1B](#)). Furthermore, morphology is of little use in the case of cryptic species—instances in which two or more species are morphologically indistinguishable but do not interbreed ([Figure 22.2](#)). Biologists therefore cannot rely on appearance alone in determining whether individual organisms are members of the same or different species. Today, biologists use several additional types of information—especially behavioral and genetic data—to differentiate species.

(A) *Hyla versicolor*

(B) *Hyla chrysoscelis*

Figure 22.2 Cryptic Species Look Alike but Do Not Interbreed. These two species of gray tree frogs cannot be distinguished by their external morphology, but they do not interbreed even when they occupy the same geographic range. (A) *Hyla versicolor* is a tetraploid species (four sets of chromosomes), whereas (B) *H. chrysoscelis* is diploid (two sets of chromosomes). And although they look alike, the males have distinctive mating calls; female frogs recognize and mate with males of their own species based on these calls.

Reproductive isolation is key

The most important factor in the divergence of sexually reproducing lineages from one another is the evolution of [reproductive isolation](#), a state in which two groups of organisms can no longer exchange genes. If individuals of group A mate and reproduce only with one another, then group A constitutes a distinct species within which genes recombine. In other words, group A is an independent evolutionary lineage—a separate branch on the tree of life.

reproductive isolation Condition in which two divergent populations are no longer exchanging genes. Can lead to speciation.

Evolutionary biologist Ernst Mayr recognized the importance of reproductive isolation in maintaining species, and so he proposed the [biological species concept](#): “Species are groups of actually or potentially interbreeding natural populations which are reproductively isolated from other such groups.” The phrase “actually or potentially” is an important element of this definition. “Actually” says that the individuals live in the same area and interbreed with one another. “Potentially” says that even though the individuals do not live in the same area, and therefore do not interbreed, other information suggests that they *would* do so if they were able to get together. This widely used species concept does not apply to organisms that reproduce asexually, and it is limited to a single point in evolutionary time.

biological species concept The definition of a species as a group of actually or potentially interbreeding natural populations that are reproductively isolated from other such groups.

(Contrast with lineage species concept; morphological species concept.)

The lineage approach takes a long-term view

Evolutionary biologists often think of species as branches on the tree of life. This idea can be termed a **lineage species concept**. In this framework for thinking about species, one species splits into two descendant species, which thereafter evolve as distinct lineages. A lineage species concept allows biologists to consider species over evolutionary time.

lineage species concept The definition of a species as a branch on the tree of life, which has a history that starts at a speciation event and ends either at extinction or at another speciation event. (Contrast with biological species concept, morphological species concept.)

A **lineage** is an ancestor—descendant series of populations followed over time. Each species has a history that starts with a speciation event by which one lineage on the tree is split into two, and ends either at extinction or at another speciation event, at which time the species produces two daughter species. The process of lineage splitting may be gradual, taking thousands of generations to complete. At the other extreme, an ancestral lineage may be split in two within a few generations (as happens with polyploidy, which we'll discuss in [Key Concept 22.3](#)). The gradual nature of some splitting events means that at a single point in time, the final outcome of the process may not be clear. In these cases, it may be difficult to predict whether the incipient species will continue to diverge and become fully isolated from their sibling species, or if they will merge again in the future.

lineage A series of populations, species, or genes descended from a single ancestor over evolutionary time.

The different species concepts are not mutually exclusive

Many named variants of these three major classes of species concepts exist. These various concepts are not incompatible; they simply emphasize different aspects of species or speciation. The morphological species concept emphasizes the practical aspects of recognizing species, although it sometimes results in underestimation or overestimation of the actual number of species. Mayr's biological species concept emphasizes that reproductive isolation is what allows sexual species to evolve independently of one another. The lineage species concept embraces the idea that sexual species are maintained by reproductive isolation, but extends the concept of a species as a lineage over evolutionary time. The species—as—lineage concept also accommodates species that reproduce asexually.

Virtually all species exhibit some degree of genetic recombination among individuals, even if recombination events are relatively rare. Significant reproductive isolation between species is therefore necessary for lineages to remain distinct over evolutionary time. Furthermore, reproductive isolation is responsible for the morphological distinctiveness of most species, because mutations that result in morphological changes cannot spread between reproductively isolated species. Therefore no matter which species concept we emphasize, the evolution of reproductive isolation is important for understanding the origin of species.

22.1 recap

Species are distinct lineages on the tree of life. Speciation is usually a gradual process as

one lineage divides into two. Over time, lineages of sexual species remain distinct from one another because they have become reproductively isolated.

learning outcomes

You should be able to:

- Explain how different species concepts may be useful for different purposes.
 - Describe the importance of reproductive isolation to understanding speciation.
-

1. Why do different biologists emphasize different attributes of species in formulating species concepts?
 2. What makes reproductive isolation such an important component of each of the species concepts discussed here?
 3. Why is the biological species concept not applicable to asexually reproducing organisms? Do you think this limits its applicability?
-

Although Charles Darwin titled his groundbreaking book *On the Origin of Species*, in fact it included very little about speciation as we understand it today. Darwin devoted most of his attention to demonstrating that individual species are altered over time by natural selection. The remaining sections of this chapter will discuss the many aspects of speciation that biologists have learned about since Darwin's time.

22.2 Speciation Is a Natural Consequence of Population Subdivision

Not all evolutionary changes result in new species. A single lineage may change over time without giving rise to a new species. Speciation requires the interruption of gene flow within a species whose members formerly exchanged genes. But if a genetic change prevents reproduction between individuals of a species, how can such a change spread through a species in the first place?

focus your learning

The Dobzhansky—Muller model explains how reproductive isolation results from the accumulation of genetic incompatibilities following a splitting of the ancestral population (interruption of gene flow).

Greater genetic differences between species are correlated with increased reproductive isolation.

Incompatibilities between genes can produce reproductive isolation

If a new allele that causes reproductive incompatibility arises in a population, it cannot spread through the population because no other individuals will be reproductively compatible with the individual that carries the new allele. So how can one reproductively cohesive lineage ever split into two reproductively isolated species? Several early geneticists, including Theodosius Dobzhansky and Hermann Joseph Muller, developed a genetic model to explain this apparent conundrum ([Figure 22.3](#)).

Figure 22.3 The Dobzhansky—Muller Model In this simple two—locus version of the model, two lineages from the same ancestral population become physically separated from each other and evolve independently. A new allele becomes fixed in each descendant lineage, but at a different locus. Neither of the new alleles is incompatible with the ancestral alleles, but the two new alleles in the two different genes are incompatible with each other. Thus the two descendant lineages are reproductively incompatible.

The Dobzhansky—Muller model is quite simple. First, assume that a single ancestral population is subdivided into two daughter populations (by the formation of a new mountain range, for instance), which then evolve as independent lineages. In one of the descendant lineages, a new allele (*A*) arises and becomes fixed (see [Figure 22.3](#)). In the other lineage, another new allele (*B*) becomes fixed *at a different gene locus*. Neither new allele at either locus results in any loss of reproductive compatibility. However, the two new forms of these two different genes have never occurred together in the same individual or population. Recall that the products of many genes must work together in an organism. It is possible that the new protein forms encoded by the two new alleles will not be compatible with each other. If individuals from the two lineages come back together after these genetic changes, they may still be able to interbreed. However, the hybrid offspring may have a new combination of genes that is functionally inferior, or even lethal. This will not happen with all new combinations of genes, but over time, isolated lineages will accumulate many allele differences at many gene loci. Some combinations of these differentiated genes will not function well together in hybrids. Thus genetic incompatibility between the two isolated lineages will develop over time.

Many empirical and experimental examples support the Dobzhansky—Muller model. This model works not only for pairs of individual genes but also for some kinds of chromosomal rearrangements. Bats of the genus *Rhogeessa*, for example, exhibit considerable variation in centric fusions of their chromosomes. The chromosomes of the various species contain the same basic chromosomal arms, but in some species two acrocentric (one—armed) chromosomes have fused at the centromere to form larger, metacentric (two—armed) chromosomes. A polymorphism in centric fusion causes few, if any, problems in meiosis because the respective chromosomes can still align and assort normally. Therefore a given centric fusion can become fixed in a lineage. However, if a *different* centric fusion becomes fixed in a second lineage, then hybrids between individuals of each lineage will not be able to produce normal gametes in meiosis ([Figure 22.4](#)). Most of the closely related species of *Rhogeessa* display different combinations of these centric fusions and are thereby reproductively isolated from one another.

Rhogeessa tumida

Figure 22.4 Speciation by Centric Fusion In this chromosomal version of the Dobzhansky—Muller model, two independent centric fusions of one—armed chromosomes occur in two sister lineages. Neither centric fusion by itself results in difficulties at meiosis, whether the fusion is found in just one or in both pairs of chromosomes. After fixation of the different fusions in each lineage, however, F_1 hybrids between the two lineages are sterile, because the three different chromosomes involved in these centric fusions cannot pair normally at meiosis in hybrids. Most of the species in the bat genus *Rhogeessa* differ from one another by such centric fusions.

Reproductive isolation develops with increasing genetic divergence

As pairs of species diverge genetically, they become increasingly reproductively isolated ([Figure 22.5](#)). Both the rate at which reproductive isolation develops and the mechanisms that produce it vary from group to group. Reproductive incompatibility has been shown to develop gradually in many groups of plants, animals, and fungi, reflecting the slow pace at which incompatible genes accumulate in each lineage. In some cases, complete reproductive isolation may take millions of years. In other cases (as with the chromosomal fusions of *Rhogeessa* described above), reproductive isolation can develop over just a few generations.

Figure 22.5 Reproductive Isolation Increases with Genetic Divergence Among pairs of *Drosophila* species, the more the species differ genetically (x axis), the greater their reproductive isolation from each other (y axis). Each dot represents a comparison of one species pair. Such positive relationships between genetic distance and reproductive isolation have been observed in many groups of plants, animals, and fungi.

Q: Why might some genetically similar species pairs exhibit high levels of reproductive isolation?

Partial reproductive isolation has evolved in many strains of plants that have been artificially isolated by humans. In 1835, Thomas Drummond collected seeds of a newly discovered species of phlox in Texas and distributed them to nurseries in Europe. The European nurseries established more than 200 true-breeding strains of Drummond's phlox that differed in flower size, flower color, and plant growth form. The breeders did not select directly for reproductive incompatibility between strains, but in subsequent experiments in which strains were crossed and seed production was measured and compared, biologists found that reproductive compatibility between strains had been reduced by 14 to 50 percent, depending on the cross—even though the strains had been isolated from one another for less than two centuries.

22.2 recap

When two parts of a population become isolated from each other by some barrier to gene flow, they begin to diverge genetically. The Dobzhansky—Muller model describes how new alleles or chromosomal arrangements that arise in the two descendent lineages can lead to genetic incompatibility, and hence reproductive isolation, of the two lineages.

learning outcomes

You should be able to:

- Make inferences and draw conclusions based on the Dobzhansky—Muller model.
- Evaluate data from two populations to determine if they are reproductively isolated.

1. The Dobzhansky-Muller model suggests that divergence among alleles at *different* gene loci leads to genetic incompatibility between species. Why is genetic incompatibility between two alleles at the same locus considered less likely?
2. Why do some combinations of chromosomal centric fusions cause problems in meiosis? Can you diagram what would happen at meiosis in a hybrid of the divergent lineages shown in [Figure 22.4](#)?
3. Assume that the reproductive isolation seen in *Phlox* strains results from lethal combinations of incompatible alleles at several loci among the various strains. Given this assumption, why might the reproductive isolation seen among these strains be partial rather than complete?

We have now seen how the splitting of an ancestral population leads to genetic divergence and reproductive incompatibility in the two descendant lineages. Next we will consider ways in which the descendant lineages could have become separated in the first place.

22.3 Speciation May Occur through Geographic Isolation or in Sympatry

Many biologists who study speciation have concentrated on geographic processes that can result in the division of an ancestral species. Splitting of the geographic range of a species is one obvious way of achieving such a division, but it is not the only way.

focus your learning

Speciation can be allopatric (resulting from the physical division of a population) or sympatric (due to disruptive selection or polyploidy).

Physical barriers give rise to allopatric speciation

Speciation that results when a population is divided by a physical barrier is known as **allopatric speciation** (Greek *allos*, “other,” + *patria*, “homeland”). Allopatric speciation is thought to be the dominant mode of speciation in most groups of organisms. The physical barrier that divides the range of a species may be a body of water or a mountain range for terrestrial organisms, or dry land for aquatic organisms—in other words, any type of habitat that is inhospitable to the species. Such barriers can form when continents drift, sea levels rise or fall, glaciers advance or retreat, or climates change. The populations separated by such barriers are often, but not always, initially large. The lineages that descend from these founding populations evolve differences for a variety of reasons, including mutation, genetic drift, and adaptation to different environments in the two areas. As a result, many pairs of closely related **sister species**—species that are each other’s closest relatives—may exist on either side of the geographic barrier. An example of a physical geographic barrier that produced many pairs of sister species was the Pleistocene glaciation that isolated freshwater streams in the eastern highlands of the Appalachian Mountains from streams in the Ozark and Ouachita Mountains (**Focus: Key Figure 22.6**). This splitting event resulted in many parallel speciation events among isolated lineages of stream-dwelling organisms.

allopatric speciation (al’ lo pat’ rick) [Gk. *allos*: other + *patria*: homeland] The formation of two species from one when reproductive isolation occurs because of the interposition of (or crossing of) a physical geographic barrier such as a river. Also called geographic speciation. (Contrast with sympatric speciation.)

sister species Two species that are each other’s closest relatives.

(A) Distribution of freshwater stream fish in the Pliocene

(B) Distribution of freshwater stream fish in the Pleistocene

Figure 22.6 Allopatric Speciation Allopatric speciation may result when an ancestral population is divided into two separate populations by a physical barrier and those populations then diverge. **(A)** Many species of freshwater stream fishes were distributed throughout the central highlands of North America in the Pliocene epoch (about 5.3—2.6 million years ago). **(B)** During the Pleistocene (about 2.6 million years ago—10,000 years ago), glaciers advanced and isolated fish populations in the Ozark and Ouachita Mountains to the west from fish populations in the highlands of the Appalachian Mountains to the east. Numerous species diverged as a result of this separation, including the ancestors of the four pairs of sister species shown here.

Q: After the retreat of the glaciers, why did the fish species in the Ozarks and Ouachitas remain reproductively isolated from those in the Appalachians to the east?

Allopatric speciation may also result when some members of a population cross an existing barrier and establish a new, isolated population. Many of the more than 800 species of *Drosophila* found in the Hawaiian Islands are restricted to a single island. We know that these species are the descendants of new populations founded by individuals dispersing among the islands when we find that the closest relative of a species on one island is a species on a neighboring island rather than a species on the same island. Biologists who have studied the chromosomes of these fruit flies estimate that speciation in this group of *Drosophila* has resulted from at least 45 such founder events ([Figure 22.7](#)).

Figure 22.7 Founder Events Lead to Allopatric Speciation The large number of species of picture-winged *Drosophila* in the Hawaiian Islands is the result of founder events: the founding of new populations by individuals dispersing among the islands. The islands, which were formed in sequence as Earth's crust moved over a volcanic "hot spot," vary in age.

The species of finches found in the islands of the Galápagos archipelago, some 1,000 km off the coast of Ecuador, are one of the most famous examples of allopatric speciation. Darwin's finches (as they are usually called, because Darwin was the first scientist to study them) arose in the Galápagos from a single South American finch species that colonized the islands. Today the Galápagos species differ strikingly not only from their closest mainland relative, but also from one another ([Figure 22.8](#)). The islands are sufficiently far apart that the birds move among them only infrequently. In addition, environmental conditions differ widely from island to island.

Some islands are relatively flat and arid; others have forested mountain slopes. Sister lineages on different islands have diverged over hundreds of thousands of years, and several feeding specializations have arisen on different islands with different environments. Although finches occasionally fly between islands, an immigrant finch population is not likely to become established unless the new environment is appropriate for its feeding specialization, and no other similar species are already present on the island. Each island now has from 1 to 4 species of finches, and biologists recognize between 14 and 18 species across the archipelago.

Figure 22.8 Allopatric Speciation among Darwin's Finches The descendants of the ancestral finch that colonized the Galápagos archipelago several million years ago evolved into many different species whose beaks are variously adapted to feed on buds, seeds, or insects.

Sympatric speciation occurs without physical barriers

Geographic isolation is usually required for speciation, but under some circumstances speciation can occur in the absence of a physical barrier. Speciation without physical isolation is called

sympatric speciation (Greek *sym*, “together with”). But how can such speciation happen? Given that speciation is usually a gradual process, how can reproductive isolation develop when individuals have frequent opportunities to mate with one another?

sympatric speciation (sim pat' rik) [Gk. *sym*: same + *patria*: homeland] Speciation due to reproductive isolation without any physical separation of the subpopulation. (Contrast with allopatric speciation.)

DISRUPTIVE SELECTION

Sympatric speciation may occur with some forms of disruptive selection (see [Key Concept 20.4](#)) in which individuals with certain genotypes have a preference for distinct microhabitats where mating takes place. For example, sympatric speciation via disruptive selection appears to be taking place in the apple maggot fly (*Rhagoletis pomonella*) of eastern North America. Until the mid—1800s, *Rhagoletis* flies courted, mated, and deposited their eggs only on hawthorn fruits. About 150 years ago, some flies began to lay their eggs on apples, which European immigrants had introduced into eastern North America. Apple trees are closely related to hawthorns, but the smell of the fruits differs, and the apple fruits appear earlier than those of hawthorns. Some early—emerging female *Rhagoletis* laid their eggs on apples, and over time, a genetic preference for the smell of apples evolved among early—emerging insects. When the offspring of these flies sought out apple trees for mating and egg deposition, they mated with other flies reared on apples, which shared the same preferences.

Today the two groups of *Rhagoletis pomonella* in the eastern United States appear to be on the way to becoming distinct species. One group mates and lays eggs primarily on hawthorn fruits, the other on apples. The incipient species are partially reproductively isolated because they mate primarily with individuals raised on the same fruit and because they emerge from their pupae at different times of the year. In addition, the apple—feeding flies now grow more rapidly on apples than they originally did. Sympatric speciation that arises from such host—plant specificity may be widespread among insects, many of which feed only on a single plant species.

POLYPLOIDY

The most common means of sympatric speciation is **Polyploidy**, or the duplication of sets of chromosomes within individuals. Polyploidy can arise either from chromosome duplication means single species (**autopolyploidy**) or from the combining of the chromosomes of two different species (**allopolyploidy**).

polyploidy (pol' lee ploid ee) The possession of more than two entire sets of chromosomes.

autopolyploidy The possession of more than two entire chromosome sets that are derived from a single species.

allopolyploidy The possession of more than two chromosome sets that are derived from more than one species.

An autopolyploid individual originates when, for example, two accidentally unreduced diploid gametes (with two sets of chromosomes) combine to form a tetraploid individual (with four sets of chromosomes). Tetraploid and diploid individuals of the same species are reproductively isolated because their hybrid offspring are triploid. Even if these offspring survive, they are usually sterile; they cannot produce normal gametes because their chromosomes do not segregate evenly during meiosis ([Figure 22.9](#)). So a tetraploid individual usually cannot produce viable offspring by mating with a diploid individual—but it *can* do so if it self—fertilizes or mates with another tetraploid. Thus polyploidy can result in complete reproductive isolation in two

generations—an important exception to the general rule that speciation is a gradual process.

Figure 22.9 Tetraploids Are Reproductively Isolated from Their Diploid

Ancestors Even if the triploid offspring of a diploid and a tetraploid parent survives and reaches sexual maturity, most of the gametes it produces have aneuploid (unbalanced) numbers of chromosomes. Such triploid individuals are effectively sterile. (For simplicity, the diagram shows only three homologous chromosomes. Most species have many more chromosomes, so viable gametes are extremely rare.)

Allopolyploids may be produced when individuals of two different (but closely related) species interbreed. Such hybridization often disrupts normal meiosis, which can result in chromosomal doubling. Allopolyploids are often fertile because each of the chromosomes has a nearly identical partner with which to pair during meiosis.

Speciation by polyploidy has been particularly important in the evolution of plants, although it has contributed to speciation in animals as well (such as the tree frogs in [Figure 22.2](#)). Botanists estimate that about 70 percent of flowering plant species and 95 percent of fern species are the result of recent polyploidization. Some of these species arose from hybridization between two species followed by chromosomal duplication and self-fertilization. Other species diverged from polyploid ancestors, so that the new species shared their ancestors' duplicated sets of chromosomes. New species arise by polyploidy more easily among plants than among animals because plants of many species can reproduce by self-fertilization. In addition, if polyploidy arises in several offspring of a single parent, the siblings can fertilize one another.

22.3 recap

Allopatric speciation results from the separation of populations by geographic barriers; it is the dominant mode of speciation among most groups of organisms. Sympatric speciation may result from disruptive selection that results in ecological isolation, but polyploidy is the most common cause of sympatric speciation among plants.

learning outcomes

You should be able to:

- Contrast the steps involved in different modes of speciation.
 - Make inferences based on an understanding of the process of allopatric speciation.
 - Diagram the relationship between geographic isolation and speciation and interpret the data to make and support predictions.
1. Explain how speciation via polyploidy can happen in only two generations.
 2. If allopatric speciation is the most prevalent mode of speciation, what do you predict about the geographic distributions of many closely related species? Does your answer differ for species that are sedentary versus highly mobile?
 3. The species of Darwin's finches shown in the phylogeny in [Figure 22.8](#) have all evolved on islands of the Galápagos archipelago within the past 3 million years. Molecular clock analysis (see [Key Concept 21.3](#)) has been used to determine the dates of the various speciation events in that phylogeny. Geological techniques for dating rock samples (see [Key Concept 24.1](#)) have been used to determine the ages of the various Galápagos islands. The table shows the number of species of Darwin's finches and the number of islands that have existed in the archipelago at several times during the past 4 million years.

Time (mya)	Number of islands	Number of finch species
0.25	18	14
0.50	18	9
0.75	9	7
1.00	6	5
2.00	4	3
3.00	4	1
4.00	3	0

- a. Plot the number of species of Darwin's finches and the number of islands in the Galápagos archipelago (dependent variables) against time (independent variable).
- b. Are the data consistent with the hypothesis that isolation of populations on newly formed islands is related to speciation in this group of birds? Why or why not?
- c. If no more islands form in the Galápagos archipelago, do you think that speciation by geographic isolation will continue to occur among Darwin's finches? Why or why not? What additional data could you collect to test your hypothesis (without waiting to see if speciation occurs)?

Most populations separated by a physical barrier become reproductively isolated only slowly and gradually. If two incipient species once again come into contact with each other, what keeps them from merging back into a single species?

22.4 Reproductive Isolation Is Reinforced When Diverging Species Come into Contact

As discussed in [Key Concept 22.2](#), once a barrier to gene flow is established, reproductive isolation will begin to develop through genetic divergence. Over many generations, differences accumulate in the isolated lineages, reducing the probability that individuals from each lineage will mate successfully with individuals in the other when they come back into contact. In this way, reproductive isolation can evolve as a by—product of the genetic changes in the two diverging lineages.

focus your learning

Reproductive isolation is reinforced in sympatry through selection for prezygotic mechanisms that prevent hybridization, which results from postzygotic mechanisms that reduce the fitness of hybrids.

Hybrid zones may contain offspring of the two hybridizing species as well as offspring of hybrid individuals.

If reproductive isolation is incomplete when incipient species come back into contact, some hybridization is likely to occur. If hybrid individuals are less fit than non—hybrids, selection will favor parents that do not produce hybrid offspring. Under these conditions, selection will result in the strengthening, or [reinforcement](#), of mechanisms that prevent hybridization.

reinforcement The evolution of enhanced reproductive isolation between populations due to natural selection for greater isolation.

Mechanisms that prevent hybridization from occurring are called [prezygotic isolating mechanisms](#). Mechanisms that reduce the fitness of hybrid offspring are called [postzygotic isolating mechanisms](#). Postzygotic isolating mechanisms result in selection against hybridization, which in turn leads to the reinforcement of prezygotic isolating mechanisms.

prezygotic isolating mechanisms Barriers to the reproductive process that occur before the union of the nuclei of two gametes (Contrast with postzygotic isolating mechanisms.)

postzygotic isolating mechanisms Barriers to the reproductive process that occur after the union of the nuclei of two gametes. (Contrast with prezygotic isolating mechanisms.)

Prezygotic isolating mechanisms prevent hybridization

Prezygotic isolating mechanisms, which come into play before fertilization, can prevent hybridization in several ways.

MECHANICAL ISOLATION

Differences in the sizes and shapes of reproductive organs may prevent the union of gametes from different species. With animals, there may be a match between the shapes of the reproductive organs of males and females of the same species, so that reproduction between individuals with mismatched reproductive structures is not physically possible. In plants, mechanical isolation may involve a pollinator. For example, some orchid species produce flowers that look and smell like the females of particular species of bee or wasp ([Figure 22.10](#)). When a male wasp visits and attempts to mate with the flower (thinking it is a female wasp of his species), his mating behavior results in the transfer of pollen to and from his body by appropriately configured anthers and stigmas on the flower. Insects that visit the flower but do not attempt to mate with it do not trigger the transfer of pollen between the insect and the flower.

Figure 22.10 Mechanical Isolation through Mimicry Many orchid species maintain reproductive isolation by means of flowers that look and smell like females of one—and only one—bee or wasp species. A male insect of the correct species must land on the flower and attempt to mate with it; only males of this particular species are physically configured to collect and transfer the orchid's pollen. The constraints of this method of pollen transfer reproductively isolate the plant from related orchid species that attract different insect pollinators. The species shown here are the two players in one such interspecific relationship; see [Figure 55.13](#) for another example.

TEMPORAL ISOLATION

Many organisms have distinct mating seasons. If two closely related species breed at different times of the year (or different times of day), they may never have an opportunity to hybridize. For example, in sympatric populations of three closely related leopard frog species, each species breeds at a different time of year ([Figure 22.11](#)). Although there is some overlap in the breeding seasons, the opportunities for hybridization are minimized.

Figure 22.11 Temporal Isolation of Breeding Seasons (A) The peak breeding seasons of three species of leopard frogs (*Rana*) overlap when the species are physically separated (allopatry). (B) Where two or more species of *Rana* live together (sympatry), overlap between their peak breeding seasons is greatly reduced or eliminated.

Q: What means of selection helps reinforce this prezygotic isolating mechanism in areas of sympatry?

BEHAVIORAL ISOLATION

Individuals may reject, or fail to recognize, individuals of other species as potential mating partners. For example, the mating calls of male frogs of related species diverge quickly ([Figure 22.12](#)). Female frogs respond to mating calls from males of their own species but ignore the calls of other species, even closely related ones. The evolution of female preferences for certain male coloration patterns among the cichlids of Lake Malawi, described at the opening story of this chapter, is another example of behavioral isolation.

Gastrophryne olivacea ■

Gastrophryne carolinensis ■

Figure 22.12 Behavioral Isolation in Mating Calls The males of most frog species

produce species-specific calls. The calls of the two closely related frog species shown here differ in their dominant frequency (a high-frequency sound wave results in a high-pitched sound; a low frequency results in a low—pitched sound). Female frogs are attracted to the calls of males of their own species.

Media Clip 22.1 **Narrowmouth Toads Calling for Mates** www.Life11e.com/mc22.1

Sometimes the mate choice of one species is mediated by the behavior of individuals of other species. For example, whether or not two plant species hybridize may depend on the food preferences of their ***pollinators**. The floral traits of plants, including their color and shape, can enhance reproductive isolation either by influencing which pollinators are attracted to the flowers or by altering where pollen is deposited on the bodies of pollinators. A plant whose flowers are pendant will be pollinated by an animal with different physical characteristics than will a plant in which the flowers grow upright (**Figure 22.13A and B**). Because each pollinator prefers (and is adapted to) a different type of flower, pollinators will rarely transfer pollen from one plant species to the other. Such isolation by pollinator behavior is seen in the mountains of California in two sympatric species of columbines (*Aquilegia*) that have diverged in flower color, structure, and orientation. *A. formosa* (**Figure 22.13C**) has pendant flowers with short spurs (spikelike, nectar—containing structures) and is pollinated by hummingbirds. *A. pubescens* (**Figure 22.13D**) has upright, lighter—colored flowers with long spurs and is pollinated by hawkmoths. The difference in pollinators means that these two species are effectively reproductively isolated even though they populate the same geographic range.

(A)

(B)

(C) *Aquilegia formosa*

(D) *A. pubescens*

Figure 22.13 Reproductive Isolating Mechanisms May Be Mediated by Species Interactions (A) This hummingbird's morphology and behavior are adapted for feeding on nectar from pendant flowers. (B) The nectar—extracting proboscis of this hawkmoth is adapted to flowers that grow upright. (C) *Aquilegia formosa* flowers are normally pendant and are pollinated by hummingbirds. (D) Flowers of *A. pubescens* are normally upright and are pollinated by hawkmoths. In addition, their long floral spurs appear to restrict access by some other potential pollinators.

HABITAT ISOLATION

When two closely related species evolve preferences for living or mating in different habitats, they may never come into contact during their respective mating periods. The *Rhagoletis* flies discussed in [Key Concept 22.3](#) experienced such habitat isolation, as did the cichlid fish that

first adapted to rocky or sandy habitats upon entering Lake Malawi, as described at the opening of this chapter.

GAMETIC ISOLATION

The sperm of one species may not attach to the eggs of another species because the eggs do not release the appropriate attractive chemicals, or the sperm may be unable to penetrate the egg because the two gametes are chemically incompatible. Thus even though the gametes of two species may come into contact, the gametes never fuse into a zygote.

Gametic isolation is extremely important for many aquatic species that spawn (release their gametes directly into the environment). For example, gametic isolation has been extensively studied in spawning sea urchins. A protein known as bindin is found in sea urchin sperm and functions in attaching (“binding”) the sperm to eggs. All sea urchin species studied produce this egg—recognition protein, but the bindin gene sequence diverges so rapidly that it becomes species—specific. Since sperm can attach only to eggs of the same species, no interspecific hybridization occurs.

Postzygotic isolating mechanisms result in selection against hybridization

Genetic differences that accumulate between two diverging lineages may reduce the survival and reproductive rates of hybrid offspring in any of several ways:

Low hybrid zygote viability. Hybrid zygotes may fail to mature normally, either dying during development or developing phenotypic abnormalities that prevent them from becoming reproductively capable adults.

Low hybrid adult viability. Hybrid offspring may have lower survivorship than non—hybrid offspring.

Hybrid infertility. Hybrids may mature into infertile adults. For example, the offspring of matings between horses and donkeys—mules—are sterile. Although otherwise healthy, mules produce no descendants.

Natural selection does not directly favor the evolution of postzygotic isolating mechanisms. But if hybrids are less fit, individuals that breed only within their own species will leave more surviving offspring than will individuals that interbreed with another species. Therefore individuals that can avoid interbreeding with members of other species will have a selective advantage, and any trait that contributes to such avoidance will be favored.

Donald Levin of the University of Texas has studied reinforcement of prezygotic isolating mechanisms in flowers of the genus *Phlox*. Levin noticed that most individuals of *P. drummondii* in most of the range of the species in Texas have pink flowers. However, where *P. drummondii* is sympatric with its close relative, the pink-flowered *P. cuspidata*, most *P. drummondii* have red flowers. No other *Phlox* species has red flowers. Levin performed an experiment whose results showed that reinforcement may explain why red flowers are favored where the two species are sympatric (**Investigating Life: Flower Color Reinforces a Reproductive Barrier in *Phlox***).

investigatinglife Flower Color Reinforces a Reproductive Barrier in *Phlox*

experiment

Original Paper: Levin, D. A. 1985. Reproductive character displacement in *Phlox*. *Evolution* 39: 1275–1281.

Most *Phlox drummondii* flowers are pink, but in regions where they are sympatric with *P. cuspidata*—which is always pink—most *P. drummondii* individuals are red. Most pollinators preferentially visit flowers of one color or the other. In this experiment, Donald Levin explored whether flower color reinforces a prezygotic reproductive barrier, lessening the chances of interspecific hybridization.

HYPOTHESIS▶ Red-flowered *P. drummondii* are less likely to hybridize with *P. cuspidata* than are pink-flowered *P. drummondii*.

METHOD

1. Introduce equal numbers of red- and pink-flowered *P. drummondii* individuals into an area with many pink-flowered *P. cuspidata*.

2. After the flowering season ends, measure hybridization by assessing the genetic composition of the seeds produced by *P. drummondii* plants of both colors.

RESULTS Of the seeds produced by pink-flowered *P. drummondii*, 38% were hybrids with *P. cuspidata*. Only 13% of the seeds produced by red-flowered individuals were genetic hybrids.

CONCLUSION▶ *P. drummondii* and *P. cuspidata* are less likely to hybridize if the flowers of the two species differ in color.

work with the data

Donald Levin of the University of Texas proposed that *Phlox drummondii* has red flowers only in locations where it is sympatric with pink-flowered *P. cuspidata* because having red flowers decreases interspecific hybridization. To test this hypothesis, Levin introduced equal numbers of red- and pink-flowered *P. drummondii* individuals into an area with many pink-flowered *P. cuspidata*. At the end of the flowering season, he assessed the genetic composition of the seeds produced by *P. drummondii*. The results are shown in the table below.

Morph (flower color)	Number of seeds (progeny)		
	<i>P. drummondii</i>	Hybrid	Total
Red	181 (87%)	27 (13%)	208
Pink	86 (62%)	53 (38%)	139

QUESTIONS

1. Check the 95% confidence intervals for the proportion of hybrid seeds in red- and pink-flowered *P. drummondii* in the graph in the Results of the experiment. There are many websites available for calculating confidence intervals; a good one is the Vassar College statistical computation site, VassarStats.net. You can go to this site and select "Proportions" from the left-hand menu, then select "The Confidence Interval of a Proportion." What are the numerical values of the 95% confidence intervals?
2. Notice that the proportions of hybrids among the seeds of red- versus pink-flowered samples are significantly different, because the 95% confidence intervals do not overlap. To quantify the significance of this difference, use the website suggested in Question 1, but select "Significance of the Difference between Two Independent Proportions" from the "Proportions" menu. What null hypothesis are you testing in this case? (See Appendix B if you need help.) What is the *P*-value of getting results at least as different as these two samples if your null hypothesis is true?
3. How would you extend or improve the experimental design of this study? What kinds of additional test sites or conditions would you want to examine? How might replicate or control sites make the study more convincing?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Likely cases of reinforcement are often detected by comparing sympatric and allopatric populations of potentially hybridizing species, as in the case of *Phlox*. If reinforcement is occurring, then sympatric populations of closely related species are expected to evolve more effective prezygotic reproductive barriers than do allopatric populations of the same species. As [Figure 22.11](#) shows, the breeding seasons of sympatric populations of different leopard frog species overlap much less than do those of allopatric populations. Similarly, the frequencies of the frog mating calls illustrated in [Figure 22.12](#) are more divergent in sympatric populations than in allopatric populations. In both cases, there appears to have been natural selection against hybridization in areas of sympatry.

Hybrid zones may form if reproductive isolation is incomplete

Unless reproductive isolation is complete, closely related species may hybridize in areas where their ranges overlap, resulting in the formation of a [hybrid zone](#). When a hybrid zone first forms, most hybrids are offspring of crosses between individuals of the two hybridizing species. However, subsequent generations include a variety of individuals with varying proportions of their genes derived from the original two species, so hybrid zones often contain recombinant

individuals resulting from many generations of hybridization.

hybrid zone A region of overlap in the ranges of two closely related species where the species may hybridize.

Detailed genetic studies can tell us why narrow hybrid zones may persist for long periods between the ranges of two species. The fire-bellied toad (*B. bombina*) lives in eastern Europe; the closely related yellow-bellied toad (*B. variegata*) lives in western and southern Europe. The ranges of the two species overlap in a long, but narrow zone stretching 4,800 km from eastern Germany to the Black Sea ([Figure 22.14](#)). Hybrids between the two species suffer from a range of defects, many of which are lethal. Those hybrids that survive often have skeletal abnormalities, such as a misshapen mouth, ribs that are fused to vertebrae, and a reduced number of vertebrae. By following the fates of thousands of toads from the hybrid zone, investigators found that a hybrid toad, on average, is only half as fit as an individual of either species. The hybrid zone remains narrow because there is strong selection against hybrids and because adult toads do not move over long distances. The zone has persisted for hundreds of years, however, because individuals of both species continue to move short distances into it, continually replenishing the hybrid population.

Figure 22.14 A Hybrid Zone The narrow zone (shown in red) in which fire—bellied

toads meet and hybridize with yellow—bellied toads has been stable for hundreds of years.

22.4 recap

Reproductive isolation may result from prezygotic or post-zygotic isolating mechanisms. Lower fitness of hybrids can lead to the reinforcement of prezygotic isolating mechanisms.

learning outcomes

You should be able to:

- Create graphical representations of hybridization frequencies and analyze data to develop hypotheses about postzygotic isolation.
- Design an experiment to investigate a given isolating mechanism.
- Relate the width and/or persistence of a hybrid zone to the fitness of hybrid offspring.

1. As shown in [Figure 22.11](#), the leopard frogs *Rana berlandieri* and *R. sphenoccephala* usually have non—overlapping breeding seasons in areas of sympatry, but where they are allopatric, both species breed in both spring and fall. When new ponds are created where the ranges of the two species come close together, frogs from previously allopatric populations may colonize the new ponds and hybridize during their overlapping breeding seasons.

Imagine you have collected and tabulated data on hybridization between these two frog species. You have sampled various life stages of frogs and their tadpoles for 2 years after an initial spring breeding season at a newly established pond. Use the data below to answer the following questions.

Life stage	<i>R.berlandieri</i>	<i>R.spheno—cephala</i>	F1 hybrids
Recently hatched tad—poles(spring, year 1)	155	125	238
Late—stage tadpoles(summer, year 1)	45	55	64
Newly metamorphosed froglets(fall, year 1)	32	42	15
Adult frogs(year 2)	10	15	1

- Create four pie charts (one for each life stage) showing the percentage of each species and the percentage of hybrids at each stage.
 - What are possible reasons for the differences in the percentages of hybrids found at each life stage? Suggest some postzygotic isolating mechanisms that are consistent with your data.
 - Over time, what changes might you expect in the breeding seasons of the two species at this particular pond, and why? How would future pie charts differ from those you created above, if your predictions about breeding seasons are correct?
2. In each of the columbine (*Aquilegia*) species shown in [Figure 22.13](#), the orientation of the flowers and the length of flower spurs are associated with a particular type of pollinator (hummingbirds or hawkmoths). Columbine flowers vary in other ways as well—for example, in color and probably in fragrance. What experiments could you design to determine the traits that various pollinators use to distinguish among the flowers of

different columbine species?

3. Why don't most narrow hybrid zones, such as the one between *Bombina bombina* and *B. variegata* shown in [Figure 22.14](#), get wider over time?

Some groups of organisms have many species, others only a few. Hundreds of species of *Drosophila* evolved in the small area of the Hawaiian Islands over about 20 million years. In contrast, there are only a few species of horseshoe crabs in the world, and only one species of ginkgo tree, even though these latter groups have persisted for hundreds of millions of years. Why do different groups of organisms have such different rates of speciation?

***connect the concepts** Some plants and their pollinators become so tightly adapted to each other that they develop mutually dependent relationships, as described in [Key Concept 29.3](#).

22.5 Speciation Rates Are Highly Variable across Life

Many factors influence the likelihood that a lineage will split to form two or more species. Therefore rates of speciation (the proportion of existing species that split to form new species over a given period) vary greatly among groups of organisms. What are some of the factors that influence the probability of a given lineage splitting into two?

focus your learning

Speciation rates vary for different groups of organisms, due to several ecological and behavioral factors.

The availability of unoccupied ecological niches increases the likelihood of adaptive radiation following colonization by a founder species.

Several ecological and behavioral factors influence speciation rates

Many factors can influence rates of speciation across groups, including the diet, behavioral complexity, and dispersal abilities of the respective species.

DIET SPECIALIZATION

Populations of species that have specialized diets may be more likely to diverge than those with more generalized diets. To investigate the effects of diet specialization on rates of speciation, Charles Mitter and colleagues compared species richness in some closely related groups of true bugs (hemipterans). The common ancestor of these groups was a predator that fed on other insects, but a dietary shift to herbivory (eating plants) evolved at least twice in the groups under study. Herbivorous bugs typically specialize on one or a few closely related species of plants, whereas predatory bugs tend to feed on many different species of insects. A high diversity of host-plant species can lead to a correspondingly high species diversity among herbivorous specialists. The Mitter et al. study showed that among these insects, the herbivorous groups do indeed contain many more species than do the related predatory groups ([Figure 22.15](#)).

Figure 22.15 Dietary Shifts Can Promote Speciation Herbivorous groups of hemipteran insects have speciated several times faster than closely related predatory groups.

POLLINATION

Speciation rates are faster in animal-pollinated than in wind-pollinated plants. Animal—pollinated groups have, on average, 2.4 times as many species as related groups pollinated by wind. Among animal—pollinated plants, speciation rates are correlated with pollinator specialization. In columbines (*Aquilegia*), the rate of evolution of new species has been about three times faster in lineages that have long nectar spurs than in lineages that lack spurs. Why do nectar spurs increase the speciation rate? Apparently it is because spurs restrict the number of pollinator species that visit the flowers, thus increasing opportunities for reproductive isolation (see [Figure 22.13](#)).

SEXUAL SELECTION

It appears that the mechanisms of sexual selection (see [Key Concept 20.2](#)) result in high rates of speciation, as we saw in the case of the cichlids of Lake Malawi. Some of the most striking examples of sexual selection are found in birds with polygynous mating systems. Birdwatchers travel thousands of miles to Papua New Guinea to witness the mating displays of male birds of paradise, which have brightly colored plumage ([Figure 22.16A](#)) and look distinctly different from females of their species—a phenomenon called sexual dimorphism. Males assemble at display grounds called leks, and females come there to choose a mate. After mating, the females leave the display grounds, build their nests, lay their eggs, and feed their offspring with no help from the males. The males remain at the lek to court more females.

Figure 22.16 Sexual Selection Can Lead to Higher Speciation Rates (A) Birds of paradise (the brightly colored male is above the female on the branch) and (B) manucodes are closely related bird groups of the South Pacific. Speciation rates are much higher among the sexually dimorphic, polygynous birds of paradise (33 species) than among the sexually monomorphic, monogamous manucodes (5 species).

The closest relatives of the birds of paradise are the manucodes ([Figure 22.16B](#)). Male and female manucodes differ only slightly in size and plumage (they are sexually monomorphic). They form monogamous pair bonds, and both sexes contribute to raising the young. There are only 5 species of manucodes, compared with 33 species of birds of paradise. By itself, this one comparison would not be convincing evidence that sexually dimorphic clades have higher rates of speciation than do monomorphic clades. However, when biologists examined all the examples of birds in which one clade is sexually dimorphic and the most closely related clade is

sexually monomorphic, the sexually dimorphic clades were significantly more likely to contain more species. But why would sexual dimorphism be associated with a higher rate of speciation?

Animals with complex sexually selected behaviors are likely to form new species at a high rate because they make sophisticated discriminations among potential mating partners. They distinguish members of their own species from members of other species, and they make subtle discriminations among members of their own species on the basis of size, shape, appearance, and behavior. Such discriminations can greatly influence which individuals are most successful in mating and producing offspring, so they may lead to rapid evolution of behavioral isolating mechanisms among populations.

DISPERSAL ABILITY

Speciation rates are usually higher in groups with poor dispersal abilities than in groups with good dispersal abilities because even narrow barriers can be effective in dividing a species whose members are highly sedentary. Until recently, the Hawaiian Islands had about 1,000 species of land snails, many of which were restricted to a single valley. Because snails move only short distances, the high ridges that separate the valleys were effective barriers to their dispersal. Unfortunately, introductions of other species and changes in habitat have resulted in the recent extinction of most of these unique Hawaiian land snails.

Rapid speciation can lead to adaptive radiation

The rapid proliferation of a large number of descendant species from a single ancestor species is called an [evolutionary radiation](#).

evolutionary radiation The proliferation of many species within a single evolutionary lineage.

Evolutionary radiations often occur when a species colonizes a new area, such as an island archipelago that contains no other closely related species, because of the large number of open ecological niches. If such a rapid proliferation of species results in an array of species that live in a variety of environments and differ in the characteristics they use to exploit those environments, it is referred to as an [adaptive radiation](#).

adaptive radiation A series of evolutionary events that results in an array (radiation) of related species that live in a variety of environments, differing in the characteristics each uses to exploit those environments.

Several remarkable adaptive radiations have occurred in the Hawaiian Islands. In addition to its 1,000 species of land snails, the native Hawaiian biota includes 1,000 species of flowering plants, 10,000 species of insects, and more than 100 bird species. However, there were no amphibians, no terrestrial reptiles, and only one native terrestrial mammal (a bat) on the islands until humans introduced additional species. The 10,000 known native species of insects on Hawaii are believed to have evolved from about 400 immigrant species; only 7 immigrant species are believed to account for all the native Hawaiian land birds. Similarly, as we saw earlier in this chapter, an adaptive radiation in the Galápagos archipelago resulted in the many species of Darwin's finches, which differ strikingly in the size and shape of their bills and, accordingly, in the food resources they use (see [Figure 22.8](#)).

The 28 species of Hawaiian sunflowers called silverswords are an impressive example of an adaptive radiation in plants ([Figure 22.17](#)). DNA sequences show that these species share a relatively recent common ancestor with a species of tarweed from the Pacific coast of North

America. Whereas all mainland tarweeds are small, upright herbs (nonwoody plants such as *Madia sativa*; see [Figure 22.17](#)), the silverswords include shrubs, trees, and vines as well as both upright and ground—hugging herbs. Silversword species occupy nearly all the habitats of the Hawaiian Islands, from sea level to above the timberline in the mountains. Despite their extraordinary morphological diversification, all silverswords are genetically very similar.

Madia sativa (tarweed)

Argyroxiphium sandwicense

Wilkesia gymnoxiphium

Figure 22.17 Rapid Evolution among Hawaiian Silverswords The Hawaiian silver — swords, three closely related genera of the sunflower family, are believed to have descended from a single common ancestor (a plant similar to the tarweed *Madia sativa*) that colonized Hawaii from the Pacific coast of North America. The four plants shown here are more closely related than they appear to be based on their morphology.

The Hawaiian silverswords are more diverse in size and shape than the mainland tarweeds because their tarweed ancestors first arrived on islands that harbored very few plant species. In particular, there were few trees and shrubs because such large—seeded plants rarely disperse to oceanic islands. Trees and shrubs have evolved from non—woody ancestors on many oceanic Islands. On the mainland, however, tarweeds live in ecological communities that contain many tree and shrub species in lineages with long evolutionary histories. In those environments, opportunities to exploit the “tree” way of life have already been preempted.

22.5 recap

Dietary specialization, pollinator spe—cialization, sexual selection, and poor dispersal abilities are correlated with high rates of speciation. Open ecological niches present opportunities for adaptive radiations.

focus your learning

You should be able to:

- Explain the factors that commonly affect speciation rates.
 - Describe the conditions that favor adaptive radiation.
-
1. How can pollinator specialization in plants and sexual selection in animals increase rates of speciation?
 2. Why do adaptive radiations often occur when a founder species invades an isolated geographic area?

The result of 3.8 billion of years of evolution has been many millions of species, each adapted to live in a particular environment and to use environmental resources in a particular way. In the next chapter we will look at the molecular processes that gave rise to that diversity.

QA If speciation typically takes thousands to , millions of years, how do biologists conduct experiments to study this process?

Although speciation usually takes thousands or millions of years, and although it is typically studied in natural settings such as Lake Malawi or in the field experiments described in Investigating Life: Flower Color Reinforces a Reproductive Barrier in *Phlox*, some aspects of speciation can be studied and observed in controlled laboratory experiments. Most such experiments use organisms with short generation times, in which evolution is expected to be relatively rapid.

William Rice and George Salt conducted an experiment in which fruit flies (*Drosophila melanogaster*) were allowed to choose food sources in different habitats. The habitats—where mating also took place—were vials in different parts of an experimental cage (Figure 22.18). The vials differed in three environmental factors: (1) light; (2) the direction (up or down) in which the fruit flies had to move to reach food; and (3) the concentrations of two aromatic chemicals, ethanol and acetaldehyde. In just 35 generations, the two groups of flies that chose the most divergent habitats had become reproductively isolated from each other, having evolved distinct preferences for the different habitats.

Figure 22.18 Evolution in the Laboratory For their experiments on the evolution of prezygotic isolating mechanisms in *Drosophila melanogaster*, Rice and Salt built an elaborate system of varying habitats contained within vials inside a large fly enclosure. Some groups of flies developed preferences for widely divergent habitats and became reproductively isolated within 35 generations.

The experiment by Rice and Salt (see American Naturalist 131: 911—917, 1988) demonstrated an example of habitat isolation as a prezygotic isolating mechanism. Even though the different habitats were in the same cage, and individual fruit flies were capable of flying from one habitat to the other, habitat preferences were inherited by offspring from their parents, and populations from the two divergent habitats did not interbreed. Similar habitat isolation is thought to have resulted in the early split between cichlids that preferred the rocky versus the sandy shores of Lake Malawi. In controlled experiments like this one, biologists can observe many aspects of the process of speciation directly.

Future directions

Biologists can now sequence entire genomes of organisms, which allows them to compare divergent genes in pairs of recently divergent species, and to identify the genes responsible for prezygotic and postzygotic isolation. These same techniques also allow researchers to detect any level of hybridization

between species. Thus we are now able to determine the genetic basis of reproductive isolation, and measure the rate at which diverging species become isolated from one another. With these advances, biologists can now appreciate the details and genetic basis for the origin of species.

▶ 22.1 Species Are Reproductively Isolated Lineages on the Tree of Life

- **Speciation** is the process by which one species splits into two or more daughter species, which thereafter evolve as distinct lineages.

speciation (spee' see ay' shun) The process of splitting one population into two populations that are reproductively isolated from one another. (Contrast with evolution.)

- The **morphological species concept** distinguishes species on the basis of physical similarities; it often underestimates or overestimates the actual number of reproductively isolated species.

morphological species concept The definition of a species as a group of individuals that look alike. (Contrast with biological species concept, lineage species concept.)

- The **biological species concept** distinguishes species on the basis of **reproductive isolation**.

biological species concept The definition of a species as a group of actually or potentially interbreeding natural populations that are reproductively isolated from other such groups. (Contrast with lineage species concept; morphological species concept.)

reproductive isolation Condition in which two divergent populations are no longer exchanging genes. Can lead to speciation.

- The **lineage species concept**, which recognizes independent evolutionary lineages as species, allows biologists to consider species over evolutionary time.

lineage species concept The definition of a species as a branch on the tree of life, which has a history that starts at a speciation event and ends either at extinction or at another speciation event. (Contrast with biological species concept, morphological species concept.)

▶ 22.2 Speciation Is a Natural Consequence of Population Subdivision

- Genetic divergence results from the interruption of gene flow within a population.
- The Dobzhansky—Muller model describes how reproductive isolation between two physically isolated populations can develop through the accumulation of incompatible genes or chromosomal arrangements. **Review Figures 22.3, 22.4, Activity 22.1**
- Reproductive isolation increases with increasing genetic divergence between populations. **Review Figure 22.5**

▶ 22.3 Speciation May Occur through Geographic Isolation or in Sympatry

- **Allopatric speciation**, which results when populations are separated by a physical

barrier, is the dominant mode of speciation. This type of speciation may follow founder events, in which some members of a population cross a barrier and found a new, isolated population. **Review Focus: Key Figure 22.6, Figures 22.7, 22.8, Animations 22.1, 22.2**

allopatric speciation (al' lo pat' rick) [Gk. *allos*: other + *patria*: homeland] The formation of two species from one when reproductive isolation occurs because of the interposition of (or crossing of) a physical geographic barrier such as a river. Also called geographic speciation. (Contrast with sympatric speciation.)

- **Sympatric speciation** results when the genomes of two groups diverge in the absence of physical isolation. It can result from disruptive selection in two or more distinct microhabitats.

sympatric speciation (sim pat' rik) [Gk. *sym*: same + *patria*: homeland] Speciation due to reproductive isolation without any physical separation of the subpopulation. (Contrast with allopatric speciation.)

- Sympatric speciation can occur within two generations via **polyploidy**, an increase in the number of chromosome sets. Polyploidy may arise from chromosome duplications within a species (**autopolyploidy**) or from hybridization that results in combining the chromosomes of two species (**allopolyploidy**). **Review Figure 22.9**

polyploid (pol' lee ploid) Possessing more than two entire sets of chromosomes.

autopolyploidy The possession of more than two entire chromosome sets that are derived from a single species.

allopolyploidy The possession of more than two chromosome sets that are derived from more than one species.

▶ 22.4 Reproductive Isolation Is Reinforced When Diverging Species Come into Contact

- **Prezygotic isolating mechanisms** prevent hybridization; **postzygotic isolating mechanisms** reduce the fitness of hybrids.

prezygotic isolating mechanisms Barriers to the reproductive process that occur before the union of the nuclei of two gametes (Contrast with postzygotic isolating mechanisms.)

postzygotic isolating mechanisms Barriers to the reproductive process that occur after the union of the nuclei of two gametes. (Contrast with prezygotic isolating mechanisms.)

- Postzygotic isolating mechanisms lead to **reinforcement** of prezygotic isolating mechanisms by natural selection. **Review Figures 22.11, 22.12, Investigating Life: Flower Color Reinforces a Reproductive Barrier in Phlox**

reinforcement The evolution of enhanced reproductive isolation between populations due to natural selection for greater isolation.

- **Hybrid zones** may form and persist if reproductive isolation between species is incomplete. **Review Figure 22.14**

hybrid zone A region of overlap in the ranges of two closely related species where the species may hybridize.

▶ 22.5 Speciation Rates Are Highly Variable across Life

- Dietary specialization, pollinator specialization, sexual selection, and dispersal ability all influence speciation rates. **Review Figures 22.15, 22.16**
- **Evolutionary radiation** refers to the rapid proliferation of descendant species from a single ancestor species. This often occurs when a species colonizes a new area with unoccupied ecological niches. If evolutionary radiation results in an array of species that live in a variety of environments and differ in the characteristics they use to exploit those environments, it is referred to as **adaptive radiation**.

evolutionary radiation The proliferation of many species within a single evolutionary lineage.

adaptive radiation A series of evolutionary events that results in an array (radiation) of related species that live in a variety of environments, differing in the characteristics each uses to exploit those environments.

► Apply What You've Learned

Review

- 2.4** Reproductive isolation is reinforced in sympatry through selection for prezygotic mechanisms that prevent hybridization, which results from postzygotic mechanisms that reduce the fitness of hybrids.

Evolutionary biologists are particularly interested in reinforcement's role in speciation because this process directly connects natural selection to the origin of species.

Different *Drosophila* species vary in the concentrations of different hydrocarbons on their cuticles. These hydrocarbons often serve as reproductive signals, with females preferring to mate with males that have the suite of hydrocarbons from the females' own species over those of other species. As they often are reproductive signals, the hydrocarbons may be the target of the selection involved in reinforcement.

Two species of *Drosophila*, *D. serrata* and *D. birchii*, are found on Australia's east coast and overlap in range. *D. serrata* populations from areas where the species encounters *D. birchii* (sympatric populations) differ from *D. serrata* populations that do not encounter the other species (allopatric populations), and these differences are likely due to reinforcement. The species do produce some hybrids, but the fitness of the hybrids is low. The graph shows concentrations of three different hypothetical hydrocarbons taken from allopatric and sympatric populations of *D. serrata* and *D. birchii*. (Numbers do not add to 100 because there are other hydrocarbons that are not shown.)

Questions

1. Based on the data, which hydrocarbon(s) show a pattern that is consistent with reinforcement? Explain your answer.
2. Suppose the allopatric populations of *D. serrata* were taken into the lab and exposed to *D. birchii* for many generations. If the artificial selection in this experiment acted like the natural selection in reinforcement, what would you expect to happen to the concentrations of each of the hydrocarbons in the allopatric populations?
3. If the artificial selection did act like the natural selection involved in reinforcement, would you expect the frequency of hybridization between allopatric populations and *D. birchii* to increase or decrease? Why?
4. Would you expect the extent of postzygotic reproductive isolation to change as a result of the artificial

selection in the experimental evolution study? Explain.

Evolutionary Theory Helps Us Make Better Flu Vaccines

Combat in World War I ended in November 1918. But the death toll from four years of war was soon surpassed by the casualties of a massive influenza epidemic that killed more than 50 million people worldwide—more than twice the number of World War I combat deaths.

The 1918–1919 pandemic was noteworthy because the death rate among young adults—who are usually less likely to die from influenza than are the elderly or the very young—was 20 times higher than in flu epidemics before or since. Why was that particular virus so deadly, especially to typically hardy individuals? The 1918 flu strain triggered an especially intense reaction in the human immune system. This overreaction meant that people with strong immune systems were likely to be more severely affected.

Usually we can count on our immune system to fight viruses, and the immune response is the basis of vaccination. Since 1945, programs to administer flu vaccines have helped keep the number and severity of influenza outbreaks in check. Last year's vaccine, however, will probably not be effective against this year's virus. New strains of flu virus are evolving continuously, producing genetic variation in the population. If these viruses did not evolve, we would become resistant to them and annual vaccination would become unnecessary. But because the viruses do evolve, biologists must develop a new and different flu vaccine each year.

The vertebrate immune response is initiated when the immune system recognizes proteins on the viral surface. Changes in viral surface proteins can allow the virus to escape immune detection. Virus strains with the greatest number of changes to their surface proteins are most likely to avoid detection and infect their hosts, and thus have an advantage over other strains. Biologists observe evolution in action by following changes in influenza virus proteins from year to year, and with this knowledge can produce more effective vaccines.

We learn a great deal about the molecular basis of evolution by examining rapidly evolving organisms such as viruses. Molecular studies of evolution, in turn, are put to practical uses, such as the development of better strategies for combating deadly diseases.

QA

Why was the 1918-1919 flu pandemic worse than any before or since?

23.1 DNA Sequences Record the History of Gene Evolution

An organism's **genome** is the full set of genes it contains, as well as any noncoding regions of the DNA (or in the case of some viruses, RNA). Most of the genes of eukaryotic organisms are found on chromosomes in the nucleus, but genes are also present in chloroplasts and mitochondria. In organisms that reproduce sexually, both males and females contribute nuclear genes, but mitochondrial and chloroplast genes are usually transmitted only via the cytoplasm of one of the two gametes (usually from the female parent).

genome (jee' nome) The complete DNA sequence for a particular organism or individual.

focus your learning

Alignment of sequences allows biologists to compare nucleotide substitutions or amino acid replacements that have occurred between individuals or species.

Simple counts of nucleotide substitutions or amino acid replacements between sequences often underestimate the underlying changes.

Genomes must be replicated to be transmitted from parents to offspring. DNA replication does not occur without error, however. Mistakes in DNA replication—mutations—provide much of the raw material for evolutionary change. Mutations are essential for the long-term survival of life because they are the initial source of the genetic variation that permits species to evolve in response to changes in their environment.

A particular allele of a gene will not be passed on to successive generations unless an individual carrying that allele survives and reproduces. The allele must function in combination with many other genes in the genome or it will quickly be selected against. Moreover, the degree and timing of a gene's expression are affected by its location in the genome. For these reasons, the genes of an individual organism can be viewed as interacting members of a group, among which there are divisions of labor but also strong interdependencies.

A genome, then, is not simply a random collection of genes in a random order along chromosomes. Rather, it is a complex set of integrated genes, regulatory sequences, and structural elements, interspersed with vast stretches of noncoding DNA that may have little direct function. Both the positions of genes and their sequences are subject to evolutionary change, as are the extent and location of noncoding DNA. All of these changes can affect the phenotype of an organism.

Biologists have now sequenced the complete genomes of a large number of organisms, including humans. The information in these sequences is helping us understand how and why organisms differ, how they function, and how they have evolved.

Evolution of genomes results in biological diversity

The field of **molecular evolution** investigates the mechanisms and consequences of the evolution of macromolecules—particularly nucleic acids (DNA and RNA) and proteins. Molecular evolutionists study relationships between the structures of genes and proteins and the functions of organisms. They also examine molecular variation to reconstruct evolutionary history and to

study the mechanisms and consequences of evolution. Students of this field ask questions such as: What does molecular variation tell us about a gene's function? Why do the genomes of different organisms vary in size? What evolutionary forces shape patterns of variation among genomes? And a crucial question from an evolutionary perspective: How do genomes acquire new functions? Investigations into the evolution of particular nucleic acids and proteins are instrumental in reconstructing the evolutionary histories of genes. Ultimately, molecular evolutionary biologists hope to explain the molecular basis of biological diversity.

molecular evolution The scientific study of the mechanisms and consequences of the evolution of macromolecules.

The evolution of nucleic acids and proteins depends on genetic variation introduced by mutations. One of several ways in which genes evolve is by means of nucleotide substitutions (the incorporation of point mutations in populations). In genes that encode proteins, nucleotide substitutions sometimes result in amino acid replacements that can change the charge, the structure, and other chemical and physical properties of the encoded protein. These changes in a protein molecule often affect the way that protein functions in the organism.

Evolutionary changes in genes and proteins can be identified by comparing nucleotide or amino acid sequences from different organisms. The longer two sequences have been evolving separately, the more differences they accumulate (bearing in mind that different genes in the same species evolve at different rates). Determining how long ago changes in nucleotide or amino acid sequences occurred is a useful step toward inferring their causes. Knowledge of the pattern and rate of evolutionary change in a given macromolecule is useful in reconstructing the evolutionary history of groups of organisms.

To compare genes or proteins from different organisms, biologists need a way to identify homologous parts of macromolecules. (Recall from [Key Concept 21.1](#) that homologous features are those shared by two or more species that have been inherited from a common ancestor.) Homologous parts of a protein can be identified by their homologous amino acid sequences. And since nucleotide sequences encode amino acid sequences, the concept of homology extends down to the level of individual nucleotide positions. Therefore one of the first steps in studying the evolution of genes or proteins is to align homologous positions in the amino acid or nucleotide sequence of interest.

Genes and proteins are compared through sequence alignment

Once the nucleotide or amino acid sequences of molecules from different organisms have been determined, they can be compared. Homologous positions can be identified only if we first pinpoint the locations of deletions and insertions that have occurred in the molecules of interest in the time since the organisms diverged from a common ancestor. A simple hypothetical example illustrates this [sequence alignment](#) technique. In [Figure 23.1](#) we compare two amino acid sequences from homologous proteins in different organisms. The two sequences at first appear to differ in both the number and identity of their amino acids. If we insert a gap after the first amino acid in sequence 2 (after leucine), however, the similarities in the two sequences become obvious. This gap represents the occurrence of one of two evolutionary events: an insertion of an amino acid in the longer protein or a deletion of an amino acid in the shorter protein. Having adjusted for this insertion or deletion event, we can see that the two sequences differ by only one amino acid at position 6 (serine or phenylalanine).

sequence alignment A method of identifying homologous positions in DNA or amino acid sequences by pinpointing the locations of deletions and insertions that have occurred since two (or more) organisms diverged from a common ancestor.

1 Two amino acid sequences seem quite different...

Sequence 1 ... Leu Arg Phe Cys Cys Ser Arg ...
Sequence 2 ... Leu Phe Cys Cys Phe Arg ...

Sequence 1 ... Leu Arg Phe Cys Cys Ser Arg ...
Sequence 2 ... Leu — Phe Cys Cys Phe Arg ...

2 ...but if we insert a gap in sequence 2, there is nearly complete alignment.

3 With this alignment established, we can compare additional sequences.

Sequence 1 ... Leu Arg Phe Cys Cys Ser Arg ...
Sequence 2 ... Leu — Phe Cys Cys Phe Arg ...
Sequence 3 ... Leu — Phe Cys Cys Phe Arg ...
Sequence 4 ... Leu Arg Ile Cys Cys Ser Arg ...
Sequence 5 ... Leu Arg Ile Cys Ala Ser Arg ...
Sequence 6 ... Leu Arg Phe Cys Ile Ser Arg ...

Similarity matrix

Numbers above the diagonal line are the number of differences.

		Sequence number					
		1	2	3	4	5	6
Sequence number	1		2	2	1	2	1
	2	5		0	3	4	3
	3	5	6		3	4	3
	4	6	4	4		1	2
	5	5	3	3	6		2
	6	6	4	4	5	5	

Numbers below the diagonal line are similarities.

Figure 23.1 Amino Acid Sequence Alignment Amino acid sequence alignment is a way of arranging protein sequences to identify regions of homology between the sequences. Gaps are inserted between the amino acid

residues to align similar residues in columns. Differences (number of amino acid differences plus insertion or deletion events) and similarities (number of identical amino acids) between each pair of aligned sequences are then summarized in a similarity matrix. Homologous DNA sequences can be aligned in a similar manner.

Activity 23.1 Amino Acid Sequence Alignment www.Life11e.com/ac23.1

Adding a single gap—that is, identifying a deletion or an insertion—aligns the two sequences in [Figure 23.1](#). Additional sequences can now be added to the alignment in a similar manner. Longer amino acid sequences, and those that have diverged more extensively, require more elaborate adjustments. Explicit models (incorporated into computer algorithms) have been developed to account for the relative probabilities of deletions, insertions, and particular amino acid replacements.

Having aligned the sequences, we can compare them by counting the number of nucleotides or amino acids that differ between them. Summing the numbers of the same and different amino acids in each pair of sequences allows us to construct a [similarity matrix](#), which gives us a measure of the minimum number of changes that have occurred since the divergence of each pair of organisms (see [Figure 23.1](#)).

similarity matrix A matrix used to compare the degree of divergence among pairs of objects. For molecular sequences, constructed by summing the number or percentage of nucleotides or amino acids that are identical in each pair of sequences.

Activity 23.2 Similarity Matrix Construction www.Life11e.com/ac23.2

Models of sequence evolution are used to calculate evolutionary divergence

The sequence comparison procedure illustrated in [Figure 23.1](#) gives a simple count of the number of similarities and differences between the proteins of two species. In the context of two aligned DNA sequences, we can count the number of differences at homologous nucleotide positions, and this count indicates the minimum number of nucleotide changes that must have occurred since the two sequences diverged from a common ancestral sequence.

Although it is useful in determining a *minimum* number of changes between two DNA sequences, the count provided by sequence alignment almost certainly underestimates the *actual* number of changes that have occurred since the sequences diverged. Any given change counted in a similarity matrix of DNA sequences may result from multiple substitution events that occurred at a given nucleotide position over time. As illustrated in [Figure 23.2](#), any of the following events may have occurred at a given nucleotide position that would not be revealed by a simple count of similarities and differences between two DNA sequences:

Figure 23.2 Multiple Substitutions Are Not Reflected in Pairwise Sequence Comparisons Two observed sequences descended from a common ancestral sequence (center) have undergone a series of substitutions. Although the two observed sequences differ by only three nucleotides (colored letters), these three differences result from a total of nine substitutions (arrows).

Multiple substitutions. More than one change has occurred at a given position between the ancestral sequence and at least one of the observed sequences.

Coincident substitutions. At a given position, different substitutions have occurred between the ancestral sequence and each observed sequence.

Parallel substitutions. The same substitution has occurred independently between the ancestral sequence and each observed sequence.

Back substitutions (also called reversions). In a variation on multiple substitutions, after a change at a given position, a subsequent substitution has changed the position back to the ancestral state.

To correct for undercounting of substitutions, molecular evolutionists have developed mathematical models that describe how DNA (and protein) sequences evolve. These models take into account the relative rates of change from one nucleotide to another. For example, *transitions* (changes between the two purines, A ↔ G, or between the pyrimidines, C ↔ T) are typically more frequent than *transversions* (a purine is replaced by a pyrimidine, or vice versa). These models also include parameters such as the different rates of substitution across different parts of a gene and the proportions of each nucleotide present in a given sequence. Once such parameters have been estimated, the model is used to correct for multiple substitutions, coincident substitutions, parallel substitutions, and back substitutions. The revised estimate

accounts for the *total* number of substitutions likely to have occurred between two sequences, which is almost always greater than the observed number of differences.

As sequence information becomes available for more and more genes in an ever-expanding database, sequence alignments can be extended across multiple homologous sequences, and the minimum number of insertions, deletions, and substitutions can be summed across homologous genes of an entire group of organisms. Similar databases have been constructed for homologous proteins. [Figure 23.3](#) shows aligned data for cytochrome c protein sequences in 33 species of animals, plants, and fungi. Such information is used extensively in determining evolutionary relationships among species.

Figure 23.3 Amino Acid Sequences of Cytochrome c The amino acid sequences shown in the table were obtained from analyses of the enzyme cytochrome c from 29 species of plants, fungi, and animals. Note the lack of variation across the sequences at positions 70-80, suggesting that this region is under strong purifying selection and that changing its amino acid sequence would impair the protein's function. The molecular models at the upper left are created from these sequences and show the three-dimensional structures of tuna and rice cytochrome c. Alpha helixes are in red, and the molecule's heme group is shown in yellow.

Experimental studies examine molecular evolution directly

Although molecular evolutionists are often interested in naturally evolved genes and proteins, molecular evolution can also be observed directly in the laboratory. Increasingly, evolutionary biologists are studying evolution experimentally. Because substitution rates are related to generation time rather than to absolute time, most of these experiments use unicellular organisms or viruses with short generations. Viruses, bacteria, and unicellular eukaryotes (such as the yeasts) can be cultured in large populations in the laboratory, and many of these organisms can evolve rapidly. In the case of some RNA viruses, the natural substitution rate may be as high as 1 substitution per 1,000 nucleotides per generation. Therefore in a virus of a few thousand nucleotides, one or more substitutions are expected (on average) every generation, and these changes can easily be determined by sequencing the entire viral genome (because of its small size). Generation time may be only tens of minutes (rather than years or decades, as in many animals), so biologists can directly observe substantial molecular evolution in a controlled population over the course of days, weeks, or months.

Experimental molecular evolutionary studies are used for a wide variety of purposes and have greatly expanded the ability of evolutionary biologists to test evolutionary concepts and principles. Biologists now routinely study evolution in the laboratory, and as we will see later in this chapter, they can use in vitro evolutionary techniques to produce novel molecules that perform new functions with industrial and pharmaceutical uses.

23.1 recap

The genomes of all organisms evolve over time. Evolutionary changes can be detected by comparing the nucleic acid and protein sequences of different species. Experimental studies of molecular evolution under controlled conditions allow biologists to study many processes of evolution directly.

learning outcomes

You should be able to:

- Align a set of sequences and create a matrix that compares the similarities and differences in the sequences.
- Demonstrate why counts of nucleotide or amino acid differences between two sequences often underestimate the actual number of changes that have occurred between the sequences.

1. Align the following sequences. Then create a matrix that compares both the number of identical nucleotides and the number of differences (including insertion and deletion events).

Sequence *a* AA T G C A GGG T A T A C G

Sequence *b* AT T C A GGG T A T AC C

Sequence *c* AT T G C A GCG T A T A A C C

Sequence *d* AT T G C A GGG T A T A C G

2. Explain why a simple count of nucleotide differences between two sequences often underestimates the actual number of nucleotide substitutions since the sequences diverged. Use an example based on the comparison of your alignment of Sequences *a* and *b* from Question 1.

We have seen that molecular evolutionists can directly observe the evolution of genomes over time, compare the genomes of different organisms, and reconstruct the changes that have occurred during their evolution. Let's turn now to the question of how genomes change, and examine some of the consequences of those changes.

2

A
su
nu
er
Fi

do
Ke
na

synonymous (silent) substitution A change of one nucleotide in a sequence to another when that change does not affect the amino acid specified (i.e., UUA → UUG, both specifying leucine). (Contrast with nonsynonymous substitution, missense substitution, nonsense substitution.)

silent substitution See synonymous substitution.

Figure 23.4 When One Nucleotide Does or Doesn't Make a Difference (A)

Synonymous (silent) substitutions do not change the amino acid specified and do not affect protein function; such substitutions are unlikely to be subject to natural selection. **(B)** Nonsynonymous (missense and nonsense) substitutions do change the amino acid sequence and are likely to have an effect (often deleterious) on protein function; such substitutions are targets for natural selection.

focus your learning

Neutral evolution is distinguished from purifying and positive selection by its lack of effect on the survival and reproduction of the organism.

The rate of fixation of neutral nucleotide changes within populations is independent of population size.

Comparing rates of synonymous and nonsynonymous substitutions can be used to identify positive and purifying selection in protein genes.

Genome sizes vary widely among organisms, even though the number of protein-coding genes shows much less variation.

A nucleotide substitution that *does* change the amino acid sequence encoded by a gene is known as a **nonsynonymous substitution** (Figure 23.4B). Nonsynonymous substitutions include **missense substitutions** that change the specified amino acid, and **nonsense substitutions** that produce a stop codon and terminate the protein. In general, nonsynonymous

substitutions are likely to be deleterious to the organism. But not every amino acid replacement alters a protein's shape and charge (and hence its functional properties), so some nonsynonymous substitutions may also be selectively neutral (or nearly so). Conversely, an amino acid replacement that confers an advantage to the organism would result in positive selection for the corresponding nonsynonymous substitution.

nonsynonymous substitution A change in a gene from one nucleotide to another that changes the amino acid specified by the corresponding codon (i.e., AGC → AGA, or serine → arginine). (Contrast with synonymous substitution.)

missense substitution A change in a gene from one nucleotide to another that results in a change to the corresponding amino acid in the encoded protein. (Contrast with synonymous substitution.)

nonsense substitution A change in a gene from one nucleotide to another that prematurely terminates translation by changing one of its codons to a stop codon. (Contrast with synonymous substitution.)

Investigators have measured the average rate of nonsynonymous nucleotide substitutions in some highly conserved protein-coding genes at about 0.9 substitutions per position per billion years. Synonymous substitutions in these genes have occurred about five times more frequently than nonsynonymous substitutions. In other words, *substitution rates are highest at nucleotide positions that do not change the amino acid being expressed* (Figure 23.5). Substitution rates are even higher in **pseudogenes**, which are duplicate, nonfunctional copies of genes.

Figure 23.5 Rates of Substitution Differ Rates of nonsynonymous substitution typically are much lower than rates of synonymous substitution and the substitution rate in pseudogenes. This pattern reflects differing levels of functional constraints.

pseudogene [Gk. *pseudes*: false] A DNA segment that is homologous to a functional gene but is not expressed because of changes to its sequence or changes to its location in the genome.

Most natural populations harbor far more genetic variation than we would expect to find if genetic variation were influenced by natural selection alone. This discovery, combined with the knowledge that many mutations do not change molecular function, stimulated the development of the neutral theory of molecular evolution.

Much of evolution is neutral

In 1968, Motoo Kimura proposed the [neutral theory](#) of molecular evolution. Kimura suggested that, at the molecular level, the majority of the variants we observe in most populations are selectively neutral; that is, they confer neither an advantage nor a disadvantage on their bearers. These neutral variants accumulate through genetic drift rather than through positive selection.

neutral theory A view of molecular evolution that postulates that most mutations do not affect the amino acid being coded for, and that such mutations accumulate in a population at rates driven by genetic drift and mutation rates.

The rate of fixation of neutral mutations by genetic drift is independent of population size. To see why this is so, consider a diploid population of size N and a neutral mutation rate μ (mu) per gamete per generation at a locus. The number of new mutations would be, on average, $\mu \times 2N$, because $2N$ gene copies are available to mutate. The probability that a given mutation will be fixed by drift alone is its frequency, which equals $1/(2N)$ for a newly arisen mutation. We can multiply these two terms to get the rate of fixation of neutral mutations (m) in a given population of N individuals:

$$m = 2N\mu \times \frac{1}{2N} = \mu$$

Therefore the rate of fixation m of neutral mutations depends only on the neutral mutation rate μ and is independent of population size. A given mutation is more likely to appear in a large population than in a small one, but any mutation that does appear is more likely to become fixed in a small population. These two influences of population size cancel each other out, so the rate of fixation of neutral mutations is equal to the mutation rate (i.e., $m = \mu$).

As long as the underlying mutation rate is constant, macromolecules evolving in separate populations should diverge from one another in neutral changes at a constant rate. Investigators have confirmed that the rate of evolution of particular genes and proteins is often relatively constant over time and can therefore be used as a “molecular clock.” As we described in [Key Concept 21.3](#), molecular clocks can be used to calculate evolutionary divergence times between species.

Although much of the genetic variation we observe in populations is the result of neutral evolution, the neutral theory does not imply that most mutations have no effect on the organism. Many mutations are never observed in populations because they are lethal or strongly detrimental to the organism and are thus quickly removed from the population through natural selection. Similarly, mutations that confer a selective advantage tend to be quickly fixed in populations, so they do not result in variation at the population level either. Nonetheless, in any population, some amino acid positions will remain constant under purifying selection, others will vary through neutral genetic drift, and still others will differ between species as a result of positive selection for change. How can these evolutionary processes be distinguished?

Positive and purifying selection can be detected in the genome

As we have just seen, substitutions in a protein-coding gene can be either synonymous or nonsynonymous, depending on whether they change the resulting amino acid sequence of the protein. The relative rates of synonymous and nonsynonymous substitutions are expected to

differ in regions of genes that are evolving neutrally, under positive selection for change, or staying unchanged under purifying selection:

If a given amino acid in a protein can be one of many alternatives (without changing the protein's function), then an amino acid replacement is *neutral* with respect to the fitness of an organism. In this case, the rates of synonymous and nonsynonymous substitutions in the corresponding DNA sequences are expected to be very similar, so the ratio of the two rates should be close to 1.

If a given amino acid position is under *positive* selection for change, the observed rate of nonsynonymous substitutions is expected to exceed the rate of synonymous substitutions in the corresponding DNA sequences.

If a given amino acid position is under *purifying* selection, then the observed rate of synonymous substitutions is expected to be much higher than the rate of nonsynonymous substitutions in the corresponding DNA sequences.

By comparing the gene sequences that encode homologous proteins from many species, scientists can determine the history and timing of synonymous and nonsynonymous substitutions. This information can be mapped on a phylogenetic tree, as we saw in [Chapter 21](#). Regions of genes that are evolving under neutral, purifying, or positive selection can be identified by comparing the nature and rates of substitutions across the phylogenetic tree.

By examining genome sequences for synonymous and nonsynonymous substitutions, biologists have determined which amino acid positions of the surface proteins of influenza viruses are evolving under positive selection (to escape immune detection in their hosts). This information allows researchers to select viruses from current influenza epidemics that are the most likely to escape human immune detection. These viruses are the ones that are most likely to give rise to the next flu epidemic, so they are the best candidates to use in vaccine production. As we discussed in the opening story, production of successful flu vaccines has greatly lowered the impact of flu epidemics in recent decades.

A study of the evolution of lysozyme illustrates how and why particular amino acid positions might be under different modes of selection ([Figure 23.6](#)). The enzyme lysozyme (see [Figure 3.9](#)) is found in almost all animals. It is produced in the tears, saliva, and milk of mammals and in the albumen (whites) of bird eggs. Lysozyme digests the cell walls of bacteria, rupturing and killing them. As a result, it plays an important role as a first line of defense against invading bacteria. Most animals defend themselves against bacteria by digesting them, which is probably why most animals have lysozyme. Some animals also use lysozyme in the digestion of food.

Figure 23.6A Convergent Molecular Evolution

Original Paper: Stewart, C.-B et al. 1987. Adaptive evolution in the stomach lysozymes of foregut fermenters. *Nature* 330: 401–404.

Langurs (a group of monkeys) and cattle are only distantly related but both have evolved foregut fermentation. They uniquely express the enzyme lysozyme in their stomachs (foreguts) to aid in breaking down bacteria that are involved in fermentation. Stewart and colleagues compared the gene sequences of lysozyme in mammals with and without foregut fermentation to see if there is convergence in the independently evolved amino acid sequences of lysozyme in langurs and cattle.

HYPOTHESIS ▶ Similar selective conditions in distantly related mammals have resulted in convergence of adaptations for foregut fermentation in the amino acid sequences of lysozyme.

METHOD

1. Isolate and sequence lysozyme from two distantly related mammal species with foregut fermentation (langur and cattle) as well as other mammals that are more closely related to either langurs or to cattle but lack foregut fermentation.

The lysozymes of langurs and cattle are convergent for 5 amino acids.

	Langur	Baboon	Human	Rat	Cattle	Horse
Langur		14	18	38	32	65
Baboon	0		14	33	39	65
Human	0	1		37	41	64
Rat	0	1	0		55	64
Cattle	5	0	0	0		71
Horse	0	0	0	0	1	

2. Tabulate the pairwise differences in the amino acid sequences. Plot the amino acid changes on the phylogenetic tree and count the number of convergent similarities between each pair of species. The results can then be plotted as a matrix.

RESULTS The matrix shows the number of all pairwise amino acid differences above the diagonal and the number of convergent similarities below the diagonal.

CONCLUSION ▶ The lysozyme sequences of the two species with foregut fermentation account for the majority of the convergent amino acid replacements observed among these species, demonstrating molecular convergence associated with the independent evolution of foregut evolution.

work with the data

Figure 23.6B Convergent Molecular Evolution

Original Paper: Stewart, C.-B., J. W. Schilling, and A. C. Wilson. 1987.

Caro-Beth Stewart and her colleagues collected lysozyme sequences from six species of mammals. A small sample of their data is shown in the table. The phylogeny of these six species is well supported from analysis of many genes and much morphological data.

	Amino acid position										
Species	2	14	17	21	50	63	75	87	117	118	130
Langur	I	K	L	K	E	Y	D	N	Q	N	V
Baboon	I	R	L	R	Q	Y	N	D	Q	N	V
Human	V	R	M	R	R	Y	N	D	Q	N	V
Rat	T	R	M	Y	Q	Y	N	D	K	N	V
Cattle	V	K	L	K	E	W	D	N	R	D	L
Horse	V	A	M	G	G	W	N	E	K	D	L
Ancestral state	V	R	M	R	Q	W	N	D	K	N	V

QUESTIONS

1. Using the phylogenetic tree (see Figure 23.6A), plot the amino acid changes across the phylogeny of the six mammals. Assume that the ancestral state is the amino acid present at the base of the tree.
2. Which amino acid positions show unique convergence between the langur and cattle lineages (i.e., the derived state is found *only* in cattle and langurs)?
3. Which additional position is convergent between cattle and the ancestor of langurs and baboons?
4. Did you detect any other convergent amino acid changes between any other pair of lineages? What does this suggest about the convergent changes you observed between cattle and langurs?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Among mammals, a mode of digestion called foregut fermentation has evolved twice. In mammals with this mode of digestion, the foregut—the posterior esophagus or the stomach—has been converted into a chamber in which bacteria break down ingested plant matter by fermentation. Foregut fermenters can extract nutrients from the otherwise indigestible cellulose that makes up a large proportion of plant tissue. Foregut fermentation evolved independently in ruminants (a group of hoofed mammals that includes cattle) and in certain leaf-eating monkeys, such as langurs. Caro-Beth Stewart knew that these evolutionary events were independent because both langurs and ruminants have close relatives that are not foregut fermenters.

In both foregut-fermenting lineages, lysozyme has been modified to play a new, nondefensive role. This lysozyme ruptures some of the bacteria that live in the foregut, releasing nutrients metabolized by the bacteria, which the mammal then absorbs. How many changes in the lysozyme molecule were needed to allow it to perform this function amid the digestive enzymes and acidic conditions of the mammalian foregut? To answer this question, Stewart and her colleagues compared the lysozyme-coding sequences in foregut fermenters with those in several of their nonfermenting relatives. They determined which amino acids differed and which were shared among the species, as well as the rates of synonymous and nonsynonymous substitutions in lysozyme genes across the evolutionary history of the sampled species.

For many of the amino acid positions of lysozyme, the rate of synonymous substitutions in the corresponding gene sequence was much higher than the rate of nonsynonymous substitutions. This observation indicates that many of the amino acids that make up lysozyme are evolving under purifying selection. In other words, there is selection against change in the protein at these positions, and the observed amino acids must therefore be critical for lysozyme function. At other positions, several different amino acids function equally well, and the corresponding gene sequences had similar rates of synonymous and nonsynonymous substitutions. The most striking finding was that amino acid replacements in lysozyme happened at a much higher rate in the lineage leading to langurs than in any other primate lineage. The high rate of nonsynonymous substitutions in the langur lysozyme gene shows that lysozyme went through a period of rapid change in adapting to the foregut of langurs. Moreover, the lysozymes of langurs and cattle share five unique amino acid replacements, all of which lie on the surface of the lysozyme molecule, well away from the enzyme's active site. Two of these shared replacements involve changes from arginine to lysine, which makes the proteins more resistant to attack by the stomach enzyme pepsin. By understanding the functional significance of amino acid replacements, molecular evolutionists can explain the observed changes in amino acid sequences in terms of changes in the functioning of the protein.

A large body of fossil, morphological, and molecular evidence shows that langurs and ruminants do not share a recent common ancestor. Yet langur and ruminant lysozymes share several amino acids that neither mammal shares with the lysozymes of its own closer relatives. The lysozymes of these two mammals have undergone convergent evolution at some amino acid positions despite their very different ancestry. The amino acids they share give these lysozymes the ability to lyse the bacteria that ferment plant material in the foregut.

The hoatzin, an unusual leaf-eating South American bird and the only known avian foregut fermenter, offers another remarkable example of the convergent evolution of lysozyme. Many birds have an enlarged esophageal chamber called a crop. The crop of the hoatzin contains lysozyme and bacteria and acts as a fermenting chamber. Many of the amino acid replacements that occurred in the adaptation of hoatzin crop lysozyme are identical to those that evolved in ruminants and langurs. Thus even though the hoatzin and foregut-fermenting mammals have not shared a common ancestor in hundreds of millions of years, they have all evolved similar adaptations in their lysozymes that enable them to recover nutrients from their fermenting bacteria.

Genome size also evolves

We know that genome size varies tremendously among organisms. Across broad taxonomic categories, there is some correlation between genome size and organismal complexity. The genome of the tiny bacterium *Mycoplasma genitalium* has only 470 genes. *Rickettsia prowazekii*, the bacterium that causes typhus, has 634 genes. *Homo sapiens*, by contrast, has about 21,000 protein-coding genes. [Figure 23.7](#) shows the numbers of genes in a sample of organisms whose genomes have been fully sequenced, arranged by their evolutionary relationships. As this figure reveals, a larger genome does not always indicate greater complexity (compare rice with the other plants, for example). It is not surprising that more complex genetic instructions are needed for building and maintaining a large multicellular organism than a small single-celled bacterium. What *is* surprising is that some multicellular organisms, such as lungfish, some salamanders, and lilies, have about 40 times as much DNA as humans do. Structurally, a lungfish or a lily is not 40 times more complex than a human. So why does genome size vary so much?

Figure 23.7 Genome Size Varies Widely This tree shows the numbers of genes from a sample of organisms whose genomes have been fully sequenced, arranged by their evolutionary relationships. Bacteria and archaea typically have fewer genes than most eukaryotes. Among eukaryotes, multicellular organisms with tissue organization (plants and animals; dark green and blue branches) have more genes than single-celled organisms (aqua branches) or multicellular organisms that lack pronounced tissue organization (yellow branches).

Differences in genome size are not so great if we take into account only the portion of the DNA that actually encodes RNAs or proteins. Although the organisms with the largest total amounts of nuclear DNA (some ferns and flowering plants) have 80,000 times as much DNA as do the bacteria with the smallest genomes, no species has more than about 100 times as many protein-coding genes as a bacterium. Therefore much of the variation in genome size lies not in the number of functional genes but in the amount of noncoding DNA ([Figure 23.8](#)).

Figure 23.8 A Large Proportion of DNA Is Noncoding Most of the DNA of bacteria and yeasts encodes RNAs or proteins, but a large percentage of the DNA of multicellular species is noncoding.

Why do the cells of most eukaryotic organisms have so much noncoding DNA? As we noted earlier, some of the noncoding DNA has a regulatory function that controls the degree or timing of expression coding genes. But the genomes of many species have far more noncoding DNA that is used for gene regulation. Does this extra noncoding DNA have a function, or is it “junk”? Many regions of noncoding DNA consist of pseudogenes (nonfunctional copies of former genes) that are carried in the genome simply because the cost of doing so is very small. These pseudogenes may become the raw material for the evolution of new genes with novel functions. Some noncoding DNA functions solely in maintaining chromosomal structure. Still other sequences consist of “selfish” transposable elements that proliferate because they reproduce faster than the host genome.

DNA does not just accumulate in genomes over time; non-critical nucleotide sequences are also lost from genomes. Some species differ so much in genome size because they lose non-critical sequences at very different rates. Investigators can use retrotransposons to estimate the rates at which species lose DNA. Retrotransposons are transposable elements (see [Figure 17.4](#)) that copy themselves through an RNA intermediate. The most common type of retrotransposon carries duplicated sequences at each end, called long terminal repeats, or LTRs. Occasionally, LTRs recombine in the host genome in such a way that the DNA between them is excised. When this happens, one recombined LTR is left behind. The number of such “orphaned” LTRs in a genome is a measure of how many retrotransposons have been lost. By comparing the number of LTRs in the genomes of Hawaiian crickets (*Laupala*) and fruit flies (*Drosophila*), investigators found that *Laupala* loses DNA more than 40 times more slowly than does *Drosophila*. Therefore it is not surprising that the genome of *Laupala* is much larger than that of *Drosophila*.

Why do species differ so greatly in the rate at which they gain or lose apparently functionless DNA? One hypothesis is that genome size is related to the rate at which the organism develops, which may be under selection pressure. Large genomes can slow down the rate of development and thus alter the relative timing of expression of particular genes. As discussed in [Key Concept](#)

[19.4](#), changes in the timing of gene expression — heterochrony—can produce major changes in phenotype. Thus although some noncoding DNA sequences may have no direct function, they may still affect the development of the organism.

Another hypothesis is that the proportion of noncoding DNA is related primarily to population size. Noncoding sequences that are only slightly deleterious to the organism are likely to be purged by selection most efficiently in species with large population sizes. In species with small populations, the effects of genetic drift can overwhelm selection against noncoding sequences that have small deleterious consequences. Therefore selection against the accumulation of noncoding sequences is most effective in species with large populations, and such species (such as bacteria and yeasts) have relatively little noncoding DNA compared with species with small populations (see [Figure 23.9](#)).

23.2 recap

The neutral theory of molecular evolution provides an explanation for the relatively constant rate of molecular change seen in many species. By examining the relative rates of synonymous and nonsynonymous substitutions in genes over time, biologists can distinguish the evolutionary mechanisms acting on individual genes. The noncoding portion of eukaryote genomes is more variable in size across species than is the coding portion.

learning outcomes

You should be able to:

- Explain why substitutions may be neutral or selective in a given organism.
- Provide a mathematical explanation for why the rate of fixation of neutral mutations is independent of population size.
- Evaluate gene sequences of protein-coding genes to identify codons that are evolving under purifying versus positive selection, and apply this knowledge to a biological problem.
- Describe the evolution of genomes in a way that incorporates consideration of noncoding DNA.

1. Over evolutionary history, many groups of organisms that inhabit caves have lost the organs of sight. For example, although surface-dwelling crayfish have functional eyes, several crayfish species that are restricted to underground habitats lack eyes. Opsins are light-sensitive proteins known to have an important function in vision (see [Chapter 45](#)), and opsin genes are expressed in eye tissues. Opsin genes are present in the genomes of eyeless, cave-dwelling crayfish. Two alternative hypotheses that might explain the presence of opsin genes in an eyeless organism are (1) the genes were inherited from an eyed ancestor, but are no longer functional; or (2) the genes have a new function other than vision. How would you investigate these two hypotheses using the sequences of the opsin genes in various species of crayfish?
2. Why is the rate of fixation of neutral mutations independent of population size?
3. An investigator compared many gene sequences encoding surface proteins from influenza viruses sampled over time and collected the data shown in the table below.

Codon position	Synonymous substitutions	Nonsynonymous substitutions
12	0	7

15	1	9
61	0	12
80	7	0
137	12	1
156	24	2
165	3	4
226	38	3

- a. Which positions encode amino acids that are likely to have changed as a result of positive selection? Explain your answer.
- b. Which positions encode amino acids that are likely to have changed as a result of purifying selection? Explain your answer.

(Hint: To calculate rates of each substitution type, consider the number of synonymous and nonsynonymous substitutions present *relative to the number of possible substitutions of each type*. There are approximately three times as many possible nonsynonymous substitutions as there are synonymous substitutions.)

4. Suggest and contrast two hypotheses for the wide diversity of genome sizes among different organisms.)

We have examined some of the ways in which organisms can lose DNA without losing gene functions. But how do organisms gain new functions through time?

***connect the concepts** The genetic code determines the amino acid that is encoded by each codon; see [figure 14.5](#)

23.3 Lateral Gene Transfer and Gene Duplication Can Produce Major Changes

As we noted in the previous section, most multicellular organisms have many more genes than do most unicellular species. But multicellular organisms evolved from unicellular ancestors. How did the numbers of genes within the genomes of multicellular organisms increase over evolutionary time? There are two primary mechanisms that can result in such increases: genes can be transferred from other species, or genes can be duplicated within species.

focus your learning

Genes can sometimes move among distantly related lineages on the tree of life.

The duplication of a gene provides opportunities for the evolution of new functions.

Some genes are present in multiple copies in the genome, and these copies often evolve together through time.

Lateral gene transfer can result in the gain of new functions

[Chapter 22](#) described how, through the process of speciation, ancestral lineages divide into descendant lineages, and it is those speciation events that are captured by the branches in the tree of life. However, there are also processes of [lateral gene transfer](#), which allow individual genes, organelles, or fragments of genomes to move horizontally from one lineage to another. Some species may pick up fragments of DNA directly from the environment. Other genes may be picked up in a viral genome and transferred to a new host when the virus becomes integrated into the new host's genome. Hybridization between species also results in the transfer of large numbers of genes.

lateral gene transfer The transfer of genes from one species to another, common among bacteria and archaea.

Lateral gene transfer can be highly advantageous to a species that incorporates novel genes from a distant relative. Genes that confer antibiotic resistance, for example, are commonly transferred among different species of bacteria. Lateral gene transfer is another way, in addition to mutation and recombination, in which species can increase their genetic variation. That genetic variation then provides the raw material on which selection acts, resulting in evolution.

A phylogenetic tree constructed from a single laterally transferred genome fragment is likely to reflect only the evolutionary history of that fragment, rather than the overall organismal phylogeny (see [Key Concept 25.1](#)). Most biologists prefer to build trees from large samples of genes or their products, so that the underlying species tree (as well as any lateral gene transfer events) can be reconstructed. Depictions of lateral gene transfer events on the underlying species tree are known as [reticulations](#).

reticulation In a phylogenetic tree, a combining of lineages (through hybridization of gene capture, for example).

The degree to which lateral gene transfer events occur in various parts of the tree of life is a matter of considerable current investigation and debate. Lateral gene transfer appears to be relatively uncommon among most eukaryote lineages, although the two major endosymbioses that gave rise to mitochondria and chloroplasts can be viewed as lateral transfers of entire bacterial genomes to the eukaryote lineage. Some groups of eukaryotes, most notably some plants, are subject to relatively high levels of hybridization among closely related species. Hybridization leads to the exchange of many genes among recently separated lineages of plants. The greatest degree of lateral transfer, however, appears to occur among bacteria. Many bacterial genes have been transferred repeatedly among lineages of bacteria, to the point that relationships among bacterial species are often hard to decipher. Nonetheless, the broad relationships of the major groups of bacteria can still be determined (as we will discuss in [Part Seven](#) of this book). Lateral transfer of genes also makes it difficult to identify the boundaries of bacterial species, which is one reason why fewer bacterial species have been named than are known to exist.

Most new functions arise following gene duplication

[Gene duplication](#) is yet another way in which genomes can acquire new functions. When a gene is duplicated, one copy of that gene is potentially freed from having to perform its original function. The initially identical copies of a duplicated gene can have any one of four subsequent fates:

gene duplication The generation of extra copies of a gene in a genome over evolutionary time. A mechanism by which genomes can acquire new functions.

- . Both copies of the gene may retain their original function (which can result in a change in the amount of gene product that is produced by the organism).
- . Both copies of the gene may retain the ability to produce the original gene product, but the expression of the genes may diverge in different tissues or at different times in development.
- . One copy of the gene may be incapacitated by the accumulation of deleterious substitutions and become a nonfunctional pseudogene, or may be eliminated from the genome altogether.
- . One copy of the gene may retain its original function while the second copy accumulates enough substitutions that it can perform a different function.

How often do [*gene duplications](#) arise, and which of these four outcomes is most likely? Investigators have found that rates of gene duplication are fast enough for a yeast or *Drosophila* population to acquire several hundred duplicate genes over the course of a million years. They have also found that most of the duplicated genes in these organisms are very young. Many extra genes are lost from a genome within 10 million years (which is rapid on an evolutionary time scale).

Some genes may be duplicated many times, resulting in large numbers of related pseudogenes scattered throughout the genome. In the human genome, the functional copy of the ribosomal protein gene *RPL21* is located on chromosome pair 13, but pseudogenes derived from it are found on most of the other chromosome pairs ([Figure 23.9](#)). Although not all genes are represented by pseudogenes, there are nearly as many known pseudogenes in the human genome as there are functional protein-coding genes.

(A) Duplications of *RPL21* gene on the human chromosomes

(B) Ratio of functional genes to pseudogenes in the human genome

Figure 23.9 Some Functional Genes Are Duplicated Many Times as Nonfunctional Pseudogenes (A) The functional gene that encodes ribosomal protein *RPL21* is located on human chromosome 13 (indicated in orange). In addition, there are many nonfunctional pseudogenes of *RPL21* in the human genome, produced through repeated duplication events (indicated in blue). (B) Although *RPL21* represents a relatively extreme example of pseudogene duplication, there are almost as many known pseudogenes in the human genome as there are functional genes.

Although many extra genes disappear rapidly, some duplication events lead to the evolution of genes with new functions. Several successive rounds of duplication and mutation may result in a **gene family**: a group of homologous genes with related functions, often arrayed in tandem along a chromosome. An example of this process is provided by the globin gene family (see [Figure 17.9](#)). The globins were among the first proteins to be sequenced and compared. Comparisons of their amino acid sequences strongly suggest that the different globins arose via gene duplications. These comparisons also allow us to estimate how long the globins have been evolving separately, because differences among these proteins have accumulated with time.

gene family A set of similar genes derived from a single parent gene; need not be on the same chromosomes. The vertebrate globin genes constitute a classic example of a gene

family.

Hemoglobin, a tetramer (four-subunit molecule) consisting of two α -globin and two β -globin polypeptide chains, carries oxygen in blood. Myoglobin, a monomer, is the primary O_2 storage protein in muscle. Myoglobin's affinity for O_2 is much higher than that of hemoglobin, but hemoglobin has evolved to be more diversified in its roles. Hemoglobin binds O_2 in the lungs or gills, where the O_2 concentration is relatively high, transports it to deep body tissues, where the O_2 concentration is low, and releases it in those tissues. With its more complex tetrameric structure, hemoglobin is able to carry four molecules of O_2 , as well as hydrogen ions and carbon dioxide, in the blood.

To estimate the time of the globin gene duplication that gave rise to the α - and β -globin gene clusters, we can create a **gene tree**—a phylogenetic tree that describes the evolutionary history of particular genes or gene families, in this case the gene sequences that encode the various globins (**Figure 23.10**). The rate of molecular evolution of globin genes has been estimated from other studies, using the divergence times of groups of vertebrates that are well documented in the fossil record. These studies indicate an average rate of divergence for globin genes of about 1 nucleotide substitution every 2 million years. By applying this rate to the globin gene tree, we can estimate the divergence time of the two globin gene clusters at about 450 million years ago.

gene tree A graphic representation of the evolutionary relationships of a single gene in different species or of the members of a gene family.

Figure 23.10 A Globin Family Gene Tree A molecular clock analysis suggests that the α -globin (blue) and β -globin (green) gene clusters diverged about 450 million years ago, soon after the origin of the vertebrates.

Q: When did the gene duplication event that gave rise to the delta and beta chains occur?

 **Activity 23.3 Gene Tree Construction** www.Life11e.com/ac23.3

Many gene duplications affect only one or a few genes at a time, but entire genomes are duplicated in polyploid organisms (which include many plants). When all the genes are

duplicated, there are massive opportunities for new functions to evolve. That is exactly what appears to have happened in the evolution of vertebrates. The genomes of the jawed vertebrates appear to have four diploid sets of many major genes, which led biologists to conclude that two genome-wide duplication events occurred in the ancestor of these species. These duplications have allowed considerable specialization of individual vertebrate genes, many of which are now highly tissue-specific in their expression.

Some gene families evolve through concerted evolution

Although the members of the globin gene family have diversified in form and function, the members of many other gene families do not evolve independently of one another. For instance, almost all organisms have many copies (up to thousands) of the ribosomal RNA genes. Ribosomal RNA (rRNA) is the principal structural element of ribosomes and, as such, has a primary role in protein synthesis. Every living species needs to synthesize proteins, often in large amounts (especially during early development). Having many copies of the rRNA genes ensures that organisms can rapidly produce many ribosomes and thereby maintain a high rate of protein synthesis.

Like all portions of the genome, ribosomal RNA genes evolve, and differences accumulate in the rRNA genes of different species. But within any one species, the multiple copies of the rRNA genes are very similar, both structurally and functionally. This similarity makes sense because, ideally, every ribosome in a species should synthesize proteins in the same way. In other words, within a given species, the multiple copies of these rRNA genes are evolving in concert with one another, a phenomenon called **concerted evolution**.

concerted evolution The common evolution of a family of repeated genes, such that changes in one copy of the gene family are replicated in other copies of the gene family, and thus evolve “in concert.” (See biased gene conversion, unequal crossing over.)

 Animation 23.1 **Concerted Evolution** www.Life11e.com/a23.1

How does concerted evolution occur? Two different mechanisms appear to be responsible. The first of these is **unequal crossing over**. When DNA is replicated during meiosis in a diploid species, the homologous chromosome pairs align and recombine by crossing over (see [Key Concept 11.4](#)). In the case of highly repeated genes, however, it is easy for genes to become displaced in alignment, since so many copies of the same genes are present on the chromosomes ([Figure 23.11A](#)). The end result is that one chromosome may gain extra copies of the repeat and the other chromosome may have fewer copies of the repeat. If a new substitution arises in one copy of the repeat, it can spread to new copies (or be eliminated) through unequal crossing over. Thus, over time, a novel substitution will either become fixed or it will be lost entirely. In either case, all copies of the repeat will remain very similar to one another.

unequal crossing over When a highly repeated gene sequence becomes displaced in alignment during meiotic crossing over, so that one chromosome receives many copies of the sequence while the second chromosome receives fewer copies. One of the mechanisms of concerted evolution. (See *also* biased gene conversion.)

(A) Unequal crossing over

(B) Biased gene conversion

Figure 23.11 Concerted Evolution Two mechanisms can produce concerted evolution of highly repeated genes. (A) Unequal crossing over results in deletions and duplications of a repeated gene. (B) Biased gene conversion can rapidly spread a new variant across multiple copies of a repeated gene.

The second mechanism that produces concerted evolution is **biased gene conversion**. This mechanism can be much faster than unequal crossing over and has been shown to be the primary mechanism for concerted evolution of rRNA genes. DNA strands are frequently broken and repaired (see [Key Concept 13.4](#)). At many times during the cell cycle, the genes for ribosomal RNA are clustered close together. If damage occurs to one of the genes, a copy of the rRNA gene on another chromosome may be used to repair the damaged copy, and the sequence that is used as a template can thereby replace the original sequence ([Figure 23.11B](#)). In many cases, this repair system appears to be biased in favor of using particular sequences as templates for repair, and thus the favored sequence rapidly spreads across all copies of the gene. In this way, changes may appear in a single copy and then rapidly spread to all the other copies.

biased gene conversion A mechanism of concerted evolution in which a DNA repair system appears biased in favor of using particular nucleotide sequences as templates for

repair, resulting in the rapid spread of the favored sequence across all copies of the gene. (See concerted evolution.)

Regardless of the mechanism responsible, the net result of concerted evolution is that the copies of a highly repeated gene do not evolve independently of one another. Mutations still occur, but once they arise in one copy, they either spread rapidly across all the copies or are lost from the genome completely. This process allows the products of each copy to remain similar over time in both sequence and function.

We have seen how the principles and methods of molecular evolution have opened new vistas in evolutionary biology. Next we will consider some of the practical applications of this field.

23.3 recap

Lateral gene transfer can result in the transfer of genetic functions between distantly related species. Gene duplication can lead to the evolution of new functions. Some highly repeated genes undergo concerted evolution, which maintains uniform functionality.

learning outcomes

You should be able to:

- Describe how genes can move among different lineages, especially among bacteria, via lateral gene transfer.
- Use a phylogenetic tree of a gene family to infer gene duplications across the history of a group of species.
- Describe how a duplicated gene provides opportunities for the evolution of new functions.
- Diagram and distinguish the two primary processes that produce concerted evolution.

1. What are some of the potential advantages of lateral gene transfer to the organisms that gain new genes by this mechanism?
2. Consider the following tree of a gene family sampled from the complete genomes of humans, chimpanzees, and gorillas. All members of the gene family are included in the tree. How many gene duplications and losses are likely to have occurred in the history of this gene family? Diagram their locations on the tree.

3. Why is gene duplication considered important for long-term evolutionary change?
4. Describe the pattern of concerted evolution among highly repeated genes, and diagram the processes that lead to concerted evolution.

***connect the concepts** [Key Concept 19.1](#) describes shared developmental mechanisms controlled by specific DNA sequences that have been modified and reshuffled to produce the remarkable diversity of plants, animals, and other organisms we know today. Similarity in the homeobox sequence common to the Hox genes suggests that the Hox genes arose through duplication of an ancestral gene, which then diverged to take on new functions.

23.4 Molecular Evolution Has Many Practical Applications

Studies of molecular evolution have practical applications throughout biology, from understanding basic aspects of biological function to studies of human health.

focus your learning

The evolutionary history of genes provides information about protein function.

The principles of in vitro evolution can be applied to produce new molecules with novel and useful functions.

Studies of molecular evolution can provide knowledge of vectors and disease transmission that is important for understanding and controlling epidemics.

Molecular sequence data are used to determine the evolutionary history of genes

A gene tree can show the evolutionary relationships of a single gene in different species, or it can trace the evolution of members of a gene family (as in [Figure 23.11](#)). The methods for constructing a gene tree are the same as those we described in [Key Concept 21.2](#) for building phylogenetic trees of species. The process involves identifying differences between genes and using those differences to reconstruct the evolutionary history of the genes. Gene trees are often used to construct phylogenetic trees of species, but the two types of trees are not necessarily equivalent. Processes such as gene duplication can give rise to differences between the phylogenetic trees of genes and species. From a gene tree, biologists can reconstruct the history and timing of gene duplication events and learn how gene diversification has resulted in the evolution of new protein functions.

All the genes of a particular gene family have similar sequences because they have a common ancestry. As we discussed in [Key Concept 21.1](#), features that are similar as a result of common ancestry are said to be homologous. When discussing gene trees, however, we usually need to distinguish between two forms of homology. Homologous genes that are found in different species and whose divergence we can trace to the speciation events that gave rise to those species are called [orthologs](#). Homologous genes in the same or different species that are related through gene duplication events are called [paralogs](#). When we examine a gene tree, the questions we wish to address determine whether we should compare orthologous or paralogous genes. If we wish to reconstruct the evolutionary history of the species that contain the genes, then our comparison should be restricted to orthologs (because they will reflect the history of speciation events). If we are interested in the changes in function that have resulted from gene duplication events, however, then the appropriate comparison is among paralogs (because they will reflect the history of gene duplication events). If our focus is on the diversification of a gene family through both processes, then we will want to include both paralogs and orthologs in our analysis.

ortholog [Gk. *ortho*: true, direct] Homologous gene whose divergence can be traced to speciation events. (Contrast with paralog.)

paralog Homologous gene whose divergence can be traced to gene duplication events. (Contrast with ortholog.)

Figure 23.12 depicts a gene tree for the members of a gene family called *engrailed* (its members encode transcription factors that regulate development). At least three gene duplications have occurred in this family, resulting in up to four different *engrailed* genes (*En*) in some vertebrate species (such as the zebrafish). All of the *engrailed* genes are homologs because they have a common ancestor. Gene duplication events have generated paralogous *engrailed* genes (*En1* and *En2*) in some lineages of vertebrates. We could compare the orthologous sequences of the *En1* group of genes to reconstruct the history of the bony vertebrates (i.e., all the vertebrate species in **Figure 23.12** except the lamprey), or we could use the orthologous sequences of the *En2* group of genes and expect the same answer (because there is only one history of the underlying speciation events). All bony vertebrates have both groups of *engrailed* genes because the two groups arose from a gene duplication event in the common ancestor of bony vertebrates. If we wanted to focus on the diversification that occurred as a result of this duplication, then the appropriate comparison would be between the paralogous genes of the *En1* versus *En2* groups.

Figure 23.12 Phylogeny of the *engrailed* Genes The *engrailed* genes are homologous because they share a common ancestor. Speciation events have generated orthologous *engrailed* genes, and gene duplication events (open circles) have generated paralogous *engrailed* genes among bony vertebrates.

Q: How many gene duplication events occurred just within the zebrafish lineage?

Gene evolution is used to study protein function

Earlier in this chapter we discussed the ways in which biologists can detect regions of genes that are under positive selection for change.

What are the practical uses of this information? Consider the evolution of the family of genes encoding ***voltage-gated sodium channels**. Sodium channels have many functions, including the control of nerve impulses in the nervous system. Sodium channels can be blocked by various toxins, such as tetrodotoxin (TTX), a neurotoxin present in the tissues of some puffer fish and several other animals. A human who eats those tissues of a puffer fish that contain TTX can become paralyzed and die because the toxin blocks sodium channels and prevents nerves and muscles from functioning.

But puffer fish have sodium channels too, so why doesn't the TTX cause paralysis in the puffer fish themselves? The sodium channels of puffer fish (and of other animals that sequester TTX, such as the rough-skinned newt shown in [Figure 20.20](#)) have evolved to become resistant to the toxin. Nucleotide substitutions in the puffer fish genome have resulted in changes in the proteins that make up the sodium channels, and those changes prevent TTX from binding to the sodium channel pore.

Several different substitutions that result in TTX resistance have evolved in the various duplicated sodium channel genes of the many species of puffer fish. Many other changes that have nothing to do with the evolution of TTX resistance have occurred in these genes as well. Biologists who study the function of sodium channels can learn a great deal about how the channels work (and about neurological diseases that are caused by mutations in the sodium channel genes) by understanding which changes have been selected for TTX resistance. They do this by comparing the rates of synonymous and nonsynonymous substitutions across the genes in various lineages that have evolved TTX resistance. In a similar manner, molecular evolutionary principles are used to understand function and diversification of function in many other proteins.

In vitro evolution is used to produce new molecules

As biologists studied the relationships among selection, evolution, and function in macromolecules, they realized that molecular evolution could be used in a controlled laboratory environment to produce new molecules with novel and useful functions. Thus were born the applications of [in vitro evolution](#).

in vitro evolution A method based on natural molecular evolution that uses artificial selection in the laboratory to rapidly produce molecules with novel enzymatic and binding functions.

Living organisms produce thousands of compounds that humans have found useful. The search for such naturally occurring compounds, which can be used for pharmaceutical, agricultural, or industrial purposes, has been termed “bioprospecting.” These compounds are the result of millions of years of molecular evolution across millions of species of living organisms. Yet biologists can also imagine molecules that *could* have evolved but, lacking the right combination of selection pressures and opportunities, have not. For instance, we might want to have a molecule that binds a particular environmental contaminant so that the contaminant can be isolated and extracted from the environment. But if the contaminant is synthetic (i.e., not produced naturally), it is unlikely that any living organism will have evolved a molecule with the function we desire. This problem was the inspiration for the field of in vitro evolution.

The principles of in vitro evolution are based on the principles of molecular evolution that we have learned from the natural world. Consider the evolution of a new RNA molecule that was produced in the laboratory using the principles of mutation and selection. This molecule's intended function was to join two other RNA molecules. That is, the lab created a ribozyme—an

RNA molecule capable of catalyzing a biochemical reaction. The process started with a large pool of random RNA sequences (10^{15} different sequences, each about 300 nucleotides long), which were then selected for any ligase activity ([Figure 23.13](#)). None were very effective ligases, but some were slightly better than others. The best of the ribozymes were selected and reverse-transcribed into cDNA (using the enzyme reverse transcriptase). The cDNA molecules were then amplified using the polymerase chain reaction (PCR; see [Figure 13.19](#)).

Figure 23.13 In Vitro Evolution Starting with a large pool of random RNA sequences, investigators produced a new ribozyme through rounds of mutation and selection for the ability to ligate RNA sequences.

PCR amplification is not perfect, and it introduced many new mutations into the pool of sequences. These sequences were then transcribed back into RNA molecules using RNA polymerase, and the process was repeated. The ligase activity of the RNAs evolved quickly;

after 10 rounds of in vitro evolution, it had increased by about 7 million times. Similar techniques have since been used to create a wide variety of molecules with novel enzymatic and binding functions.

Molecular evolution is used to study and combat diseases

Many of the most problematic human diseases are caused by living, evolving organisms that present a moving target for modern medicine. Recall the example of influenza described in the opening story of this chapter and that of HIV in [Chapter 21](#). The control of these and many other human diseases depends on techniques that can track the evolution of pathogenic organisms over time.

The transportation advances of the past century have allowed humans to move around the world with unprecedented speed and frequency. Unfortunately, this mobility has allowed pathogens to be transmitted among human populations, and between humans and other animals, at increasing rates. Cross-species transmission of viruses has led to the global emergence of many “new” diseases.

In the opening of this chapter, we described the devastating influenza pandemic of 1918-1919. Michael Worobey and his colleagues used evolutionary analyses of influenza genomes to explore the reasons why this particular flu epidemic was so much more severe than any before or since (**Investigating Life: Why Was the 1918-1919 Influenza Pandemic So Severe?**). They reconstructed the evolutionary history of influenza viruses in birds, pigs, horses, and humans and found that influenza viruses have repeatedly been transferred from birds to the various mammals. Most cross-species transfers have been accompanied by a major epidemic in the new host. The 1918-1919 epidemic occurred immediately after such a transfer between hosts. Human immune systems had no experience with the newly acquired virus, and the strong resulting reaction caused many of the strongest symptoms and deaths. Now that cross-species transmission has been associated with major flu epidemics, health workers around the world are constantly monitoring flu cases for indications of new cross-species transmissions. When emerging viruses are identified early on, efforts to control and eradicate them have a good chance of being successful. So far, our understanding of molecular evolution has prevented a repeat of the devastating flu pandemic of 1918-1919.

Studies of the genomes of many infectious agents have advanced our understanding and treatment of the diseases they cause. For example, rodent-borne hantaviruses were identified as the source of widespread respiratory illnesses, and the virus (and its host) that causes Sudden Acute Respiratory Syndrome (SARS) was identified using evolutionary comparisons of genes. Studies of the origins, the timing of emergence, and the global diversity of many human pathogens depend on the principles of molecular evolution, as do the efforts to develop and use effective vaccines against these pathogens. For example, the techniques used to develop modern polio vaccines, as well as the methods used to track their effectiveness in human populations, rely on molecular evolutionary approaches.

 **investigatinglife** why was the 1918-1919
influenza pandemic so severe?

experiment

Original Papers: Tumpey, T. M. et al. 2005. Characterization of the reconstructed 1918 Spanish influenza pandemic virus. *Science* 310: 77–80.

Worobey, M., G.-Z. Han, and A. Rambaut. 2014. A synchronized global sweep of the internal genes of modern avian influenza virus. *Nature* 508: 254–257.

As conveyed in the story that opens this chapter, the 1918–1919 influenza pandemic killed more than 50 million people worldwide—many more than the number of World War I-related combat deaths. Unlike flu epidemics before or since, the flu viruses that circulated in the 1918–1919 epidemic triggered an especially intense reaction in the human immune system. What was different about the flu viruses circulating at that time?

Terrence Tumpey and his colleagues at the Centers for Disease Control and Prevention isolated and sequenced a complete flu virus from biopsies of 1918 victims of the pandemic. Michael Worobey of the University of Arizona and his colleagues then analyzed and compared the genomes of flu viruses that have been collected from 1918 to the present, from birds, pigs, horses, and humans. The viruses are largely transmitted within each of these host groups, but rarely jump between host groups. Worobey and his colleagues reconstructed the phylogeny of the viruses to determine if the 1918 virus had recently “jumped” into human populations from another species.

HYPOTHESIS▶ The 1918–1919 influenza epidemic was so severe because the 1918 virus had recently moved into human populations from another species.

METHOD

1. Sequence the genomes of influenza viruses isolated from samples of birds, pigs, horses, and humans throughout the past century.
2. Reconstruct a phylogenetic tree based on sequences of the polymerase protein PA from the influenza virus genomes. Repeat this analysis for each of the genes in the genome. (Note that only the results based on PA are shown below.)
3. Determine the rate of evolution of the influenza viruses in each species, and use this information to conduct a molecular clock analysis to date the origins of each cross-species transmission.

RESULTS

Species-specific rates of the polymerase protein PA from the genome of influenza viruses in each host species:

Time-calibrated phylogeny of the PA gene from influenza:

Viruses represented by blue lineages were isolated from birds; green lineages from pigs; orange lineages from horses; and red lineages from humans. The triangles represent many closely related sequences sampled from the respective species in the time period indicated; the width of the triangle is proportional to the number of sequences analyzed. The 1918 human influenza virus is labeled “1918.”

CONCLUSION▶ What would you conclude about the 1918–1919 influenza pandemic from these results? Explore the possibilities in the following work with the data.

work with the data

Original Paper: Worobey, M., G.-Z. Han and A. Rambaut. 2014.

Michael Worobey and his colleagues were able to reconstruct many of the cross-species transmissions of influenza virus that have occurred over the past 150 years, and to determine a likely reason that the 1918–1919 pandemic in humans was so severe. Can you replicate their conclusions?

QUESTIONS

1. All the influenza viruses shown in the tree in the experiment are thought to have arisen in one group of host animals. Which group of animals do you think is the original source of the virus, and why?

2. How many cross-species transmissions are shown on the tree? What hosts were involved (as source and recipient) of each transmission event?
3. What do you think is a likely explanation for the severity of the 1918–1919 influenza pandemic in humans?
4. Influenza was known in humans well before the 1918–1919 pandemic. Why do you think that no human influenza viruses are indicated on the tree before about 1918?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

In the future, molecular evolution will become even more critical to the identification of human (and other) diseases. Once have collected data on the genomes of enough organisms, it will be possible to identify an infection by sequencing a portion of the infecting organism’s genome and comparing this sequence with other sequences on an evolutionary tree. At present it is difficult to identify many common viral infections (those that cause “colds,” for instance). As genomic databases and evolutionary trees increase, however, automated methods of sequencing and rapid phylogenetic comparison of the sequences will allow us to identify and treat a much wider array of human illnesses.

23.4 recap

Studies of molecular evolution have provided biologists with new tools to understand the functions of macromolecules and how those functions can change over time. These tools can be used to develop synthetic molecules and to identify and combat human diseases.

learning outcomes

You should be able to:

- Describe how studies of molecular evolution are used to understand protein function.
- Design in vitro evolution protocols that will generate sequences with desired functional characteristics.
- Evaluate evolutionary relationships among viral sequences to understand the evolution and transmission of a viral disease.

1. How can gene evolution be used to study protein function? Describe a specific example.
2. What are the key elements of in vitro evolution, and how do these elements correspond to natural evolutionary processes?
3. How are principles of evolutionary biology used to identify emerging diseases?

Now that we have discussed how organisms and biological molecules evolve, we are ready to consider the broader evolutionary history of life on Earth. [Chapter 24](#) will describe the long-term evolutionary changes that have given rise to all of life's diversity.

investigatinglife

Why was the 1918-1919 flu pandemic worse than any before or since?

Many different strains of influenza virus circulate among human populations and other vertebrate hosts each year, but only a few of those strains survive and produce descendants. One of the ways in which influenza strains differ is in the configuration of proteins on their surface. These surface proteins are the targets of recognition by the host immune system. When changes occur in the surface proteins of an influenza virus, the host immune system may no longer recognize the invading virus, so that virus is more likely to replicate successfully. Those virus strains with the greatest number of changes to their surface proteins are most likely to escape detection by the host immune system, and are therefore most likely to spread among the host population and result in future flu epidemics. In other words, there is positive selection for change in the surface proteins of influenza viruses.

As demonstrated by data presented in *Investigating Life: Why Was the 1918-1919 Influenza Pandemic So Severe?*, the 1918-1919 flu epidemic occurred shortly after the cross-species transfer of an avian flu virus into human populations. For humans, this was a new virus, different than any influenza viruses that had circulated before in human populations. As human immune systems had no previous exposure to this virus, they had not yet developed effective immune defenses. The virus overstimulated human immune systems, which led to secondary complications and death. Today, investigators carefully monitor influenza viruses circulating in human populations around the world. Early detection of new cross-species transmissions from birds or pigs into human populations is the key to their elimination before they can result in new global human influenza pandemics.

Future directions

By comparing the survival and proliferation rates of influenza virus strains that have different gene sequences coding for surface proteins, biologists can study the adaptation of the viruses over time. If biologists can predict which of the currently circulating flu virus strains are most likely to escape host detection, they can then identify the strains that are most likely to be involved in upcoming influenza epidemics and can target those strains for vaccine production.

How can biologists make such predictions? By determining the ratio of synonymous to nonsynonymous substitutions in genes that encode viral surface proteins, biologists can detect which codon changes (i.e., mutations) are under positive selection. They can then assess which of the currently circulating flu strains show the greatest number of changes in these positively selected codons. It is these flu strains that are most likely to survive, proliferate, and lead to the flu epidemics of the future, so they are the logical targets for new vaccines. This practical application of evolutionary theory leads to more effective flu vaccines—and thus fewer illnesses and influenza-related deaths each year.

▶ 23.1 DNA Sequences Record the History of Gene Evolution

- A **genome** is an organism's full set of genes, regulatory sequences, and structural elements as well as noncoding DNA.

genome (jee' nome) The complete DNA sequence for a particular organism or individual.

- The field of **molecular** evolution concerns relationships between the structures of genes and proteins and the functions of organisms.
- **Sequence alignments** of proteins or nucleic acids from different organisms allow us to compare the sequences and identify homologous positions. Review [Figure 23.1](#), [Activity 23.1](#)

sequence alignment A method of identifying homologous positions in DNA or amino acid sequences by pinpointing the locations of deletions and insertions that have occurred since two (or more) organisms diverged from a common ancestor.

- The minimum number of changes between sequences can be calculated from a **similarity matrix**. Models of sequence evolution can be used to account for changes that cannot be observed directly. Review [Figure 23.2](#), [Activity 23.2](#)

similarity matrix A matrix used to compare the degree of divergence among pairs of objects. For molecular sequences, constructed by summing the number or percentage of nucleotides or amino acids that are identical in each pair of sequences.

▶ 23.2 Genomes Reveal Both Neutral and Selective Processes of Evolution

- **Nonsynonymous substitutions** of nucleotides result in changes to the amino acid sequences of proteins, but **synonymous substitutions** do not. Review [Figure 23.4](#)

nonsynonymous substitution A change in a gene from one nucleotide to another that changes the amino acid specified by the corresponding codon (i.e., AGC → AGA, or serine → arginine). (Contrast with synonymous substitution.)

- The **neutral** theory of molecular evolution states that much of the molecular change in nucleotide sequences does not change genome function. The rate of fixation of neutral mutations is independent of population size and is equal to the mutation rate.
- Positive selection for change in a protein-coding gene may be detected by a higher rate of nonsynonymous than synonymous substitutions. The reverse is true of purifying selection.
- Common selective constraints can lead to convergent evolution of amino acid sequences in distantly related species. Review [Figure 23.6](#)

- The total size of genomes varies much more widely across multicellular species than does the number of functional genes. Review [Figures 23.7, 23.8](#)

▶ 23.3 Lateral Gene Transfer and Gene Duplication Can Produce Major Changes

- [Lateral gene transfer](#) can result in the rapid acquisition of new functions from distantly related species.

lateral gene transfer The transfer of genes from one species to another, common among bacteria and archaea.

- [Gene duplications](#) can result in increased production of a gene's product, in nonfunctional [pseudogenes](#), or in new gene functions. Several rounds of gene duplication can give rise to multiple genes with related functions, collectively known as a gene family. Review [Figures 23.9, 23.10](#)

gene duplication The generation of extra copies of a gene in a genome over evolutionary time. A mechanism by which genomes can acquire new functions.

pseudogene [Gk. *pseudes*: false] A DNA segment that is homologous to a functional gene but is not expressed because of changes to its sequence or changes to its location in the genome.

- Gene trees describe the evolutionary history of particular genes or gene families. See [Activity 23.3](#)
- Some highly repeated genes undergo concerted evolution, in which the multiple copies within the genome maintain their similarity, even as the genes diverge among species. Review [Figure 23.11](#), [Animation 23.1](#)

▶ 23.4 Molecular Evolution Has Many Practical Applications

- [Orthologs](#) are genes that are related through speciation events, whereas [paralogs](#) are genes that are related through gene duplication events. Review [Figure 23.12](#)

ortholog [Gk. *ortho*: true, direct] Homologous gene whose divergence can be traced to speciation events. (Contrast with paralog.)

paralog Homologous gene whose divergence can be traced to gene duplication events. (Contrast with ortholog.)

- Protein function can be studied by examining gene evolution. Detection of positive selection can be used to identify molecular changes that have resulted in functional changes.
- [In vitro evolution](#) is used to produce synthetic molecules with particular desired functions. Review [Figure 23.13](#)

in vitro evolution A method based on natural molecular evolution that uses artificial selection in the laboratory to rapidly produce molecules with novel enzymatic and binding functions.

- Many diseases are identified, studied, and combated through molecular evolutionary investigations. **Review Investigating Life: Why Was the 1918-1919 Influenza**

Pandemic So Severe?

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

- 3.1 Simple counts of nucleotide substitutions or amino acid replacements between sequences often underestimate the underlying changes.
- 3.1 The rate of fixation of neutral nucleotide changes within populations is independent of population size.
- 3.1 Comparing rates of synonymous and nonsynonymous substitutions can be used to identify positive and purifying selection in protein genes.

By studying molecular evolution patterns of genes, biologists are able to make inferences about various types of natural selection operating on them. These inferences are important to our understanding of how genes function and how they evolve through time in response to selection for new functions or new conditions.

A hypothetical gene encodes a transcription factor in various *Drosophila* species. The phylogeny of these species is shown below, with divergence times shown in millions of years.

One exon of this gene has been sequenced in the four species. Below is a matrix representing the number of synonymous (above the diagonal) and nonsynonymous (below the diagonal) substitutions between pairs of species. For instance, there are 21 synonymous substitutions between *D. melanogaster* and *D. yakuba*. There are 2000 nonsynonymous and 600 synonymous sites in this exon, and there are five generations per year.

	<i>D. ananassae</i>	<i>D. yakuba</i>	<i>D. melanogaster</i>	<i>D. simulans</i>
<i>D. ananassae</i>		54	56	52
<i>D. yakuba</i>	20		21	16
<i>D. melanogaster</i>	17	7		10
<i>D. simulans</i>	17	5	3	

Answers to the questions below will provide information about the types of selection operating

on this transcription factor and, potentially, its function.

Questions

1. Graph the relationship between the number of synonymous substitutions and the years of divergence between each pair of species. Label both axes. Use this graph to estimate the rates of synonymous substitutions per million years and per generation for the whole exon and on a per-site basis. Remember that evolution is occurring on both lineages.
2. Assume that synonymous substitutions are neutral. What is the expected per-site mutation rate based on the answer in Question 1?
3. Houseflies (*Musca domestica*) diverged from *D. melanogaster* about 90 million years ago. Suppose there are 174 synonymous substitutions between these two taxa. Assume that the number of generations remains constant at five per year across these species. Calculate the *expected* number of synonymous substitutions between these two species given the calculated synonymous substitution rate from Question 1, the time of divergence, and the number of generations per year. Provide an explanation for why there is a discrepancy between the observed and expected values, continuing to assume that the mutations are completely neutral. (Hint: Consider what you know about substitution patterns.)
4. Calculate the average per-site, per-generation, nonsynonymous substitution rate between *D. ananassae* and the other three species. Based on the differences between this rate and the synonymous substitution rate calculated in Question 1, what can you infer about the type of selection operating on the nonsynonymous sites?
5. Suppose a biologist asserts that this transcription factor is actually a pseudogene in flies. Based on the information you have obtained, do you agree with this biologist? Why or why not?

When Giant Insects Ruled the Skies

The largest dragonflies alive today have wingspans that can be covered by a human hand. Three hundred million years ago, however, dragonflies such as *Meganeuropsis permiana* had wingspans of more than 70 centimeters—well over 2 feet, matching or exceeding the wingspans of many modern birds of prey. These dragonflies were the largest flying predators of their time. Below, an artist's reconstruction of *M. permiana* is shown at the same scale as a modern dragonfly.

No flying insects alive today are anywhere near this size. But during the Carboniferous and Permian geological periods, 350 to 250 million years ago, many groups of flying insects contained gigantic species. *Meganeuropsis* probably ate huge mayflies and other giant flying insects that shared its home in the Permian swamps. These enormous insects were themselves eaten by giant amphibians. None of these insects or amphibians would be able to survive on Earth today. The oxygen concentrations in Earth's atmosphere were about 50 percent higher then than they are now, and those high oxygen concentrations are thought to have been necessary to support giant insects and their huge amphibian predators.

Paleontologists have uncovered fossils of *Meganeuropsis permiana* in the rocks of Kansas. How do we know the age of these fossils, and how can we know how much oxygen that long-vanished atmosphere contained? The layering of rocks allows us to tell their ages relative to one another, but it does not by itself indicate a given layer's absolute age.

Scientists have developed sophisticated techniques that use the decay rates of radioisotopes, the ratios of certain molecules in rocks, and changes in Earth's magnetic field to infer conditions and events in the remote past and to date them accurately. It is those methods that allow us to age the fossils of *Meganeuropsis* and to calculate the concentration of oxygen in Earth's atmosphere at the time.

Earth is about 4.5 billion years old, and life has existed on it for about 3.8 billion of those years. That means human civilizations have occupied Earth for less than 0.0003 percent of the history of life. Discovering what happened before humans were around is an ongoing and exciting area of science.

QA How can modern experiments test hypotheses about the evolutionary impact of ancient environmental changes?

24.1 Events in Earth's History Can Be Dated

Some evolutionary changes happen rapidly enough to be studied directly and manipulated experimentally. Plant and animal breeding by agriculturalists and the evolution of surface proteins in influenza viruses are examples of rapid, shortterm evolution that we have discussed in previous chapters. Such changes can take place in months, years, decades, or centuries. Other evolutionary changes, such as the appearance of new species and major evolutionary lineages, usually take place over a **geological time scale** (Table 24.1).

geological time scale The division of Earth's history into ordered, named periods of time, based on major biotic and abiotic changes.

table 24.1 Earth's Geological History

Eon	Era	Period	Onset	Major physical changes on Earth
Phanerozoic (~0.5 billion years long)	Cenozoic	Quaternary (Q)	2.6 mya	Cold/dry climate; repeated glaciations
		Tertiary (T)	65.5 mya	Continents near current positions; climate cools
	Mesozoic	Cretaceous (K)	145.5 mya	Laurasian continents attached to one another; Gondwana begins to drift apart; meteorite strikes near current Yucatán Peninsula at end of period
		Jurassic (J)	201.6 mya	Two large continents form: Laurasia (north) and Gondwana (south); climate warm
		Triassic (Tr)	251.0 mya	Pangaea begins to drift apart; hot/humid climate
	Paleozoic	Permian (P)	299 mya	Extensive lowland swamps; O ₂ levels 50% higher than present; by end of period continents aggregate to form Pangaea, and O ₂ levels drop rapidly
		Carboniferous (C)	359 mya	Climate cools; marked latitudinal climate gradients
		Devonian (D)	416 mya	Continents collide at end of period; giant meteorite probably strikes Earth
		Silurian (S)	444 mya	Sea levels rise; two large land masses emerge; hot/humid climate
		Ordovician (O)	488 mya	Massive glaciation; sea level drops 50 meters
		Cambrian (C)	542 mya	Atmospheric O ₂ levels approach current levels
Proterozoic	Collectively called the Precambrian (~4 billion years long)		2.5 bya	Atmospheric O ₂ levels increase from negligible to about 18%; "snowball Earth" from about 750 to 580 mya
Archean			3.8 bya	Earth accumulates more atmosphere (still almost no O ₂); meteorite impacts greatly reduced
Hadean			4.5–4.6 bya	Formation of Earth; cooling of Earth's surface; atmosphere contains almost no free O ₂ ; oceans form; Earth under almost continuous bombardment from meteorites

Note: mya, million years ago; bya, billion years ago.

focus your learning

Geologists use several methods to date ancient events.

Scientists have developed a geological time scale.

Geologists construct geological maps based on the age of rocks.

To understand long-term patterns of evolutionary change, we must not only think in time scales spanning many millions of years, but also consider events and conditions very different from those we observe today. Earth of the distant past was so unlike our present Earth that it would seem like a foreign planet inhabited by strange organisms. The continents were not where they

are now, and climates were sometimes dramatically different from those of today. We know this because much of Earth's history is recorded in its rocks.

We cannot tell the ages of rocks just by looking at them, but we can visually determine the ages of rocks *relative to one another*. The first person to formally recognize this fact was the seventeenth-century Danish physician Nicolaus Steno. Steno realized that in undisturbed [sedimentary rocks](#) (rocks formed by the accumulation of sediments), the oldest layers of rock, or **strata** (singular *stratum*), lie at the bottom, and successively higher strata are progressively younger.

sedimentary rock Rock formed by the accumulation of sediment grains on the bottom of a body of water. Often contain stratified fossils that allow geologists and biologists to date evolutionary events relative to each other.

Geologists subsequently combined Steno's insight with their observations of fossils contained in sedimentary rocks. They developed the following principles of [stratigraphy](#):

stratigraphy The study of geological strata.

Fossils of similar organisms are found in widely separated places on Earth.

Certain fossils are always found in younger strata, and certain other fossils are always found in older strata.

Organisms found in younger strata are more similar to modern organisms than are those found in older strata.

These patterns revealed much about the relative ages of sedimentary rocks and the fossils they contained, as well as patterns in the evolution of life. But the geologists still could not determine the age of particular rocks. A method for absolute dating of rocks—that is, determining their actual age rather than just their age relative to one another—did not become available until after radioactivity was discovered at the beginning of the twentieth century.

Major events in the history of life

Humans evolve; many large mammals become extinct

Diversification of birds, mammals, flowering plants, and insects

Dinosaurs continue to diversify; mass extinction at end of period (~76% of species lost)

Diverse dinosaurs; radiation of ray-finned fishes; first fossils of flowering plants

Early dinosaurs; first mammals; marine invertebrates diversify; mass extinction at end of period (~65% of species lost)

Reptiles diversify; giant amphibians and flying insects present; mass extinction at end of period (~96% of species lost)

Extensive fern/horsetail/giant club moss forests; first reptiles; insects diversify

Jawed fishes diversify; first insects and amphibians; mass extinction at end of period (~75% of marine species lost)

Jawless fishes diversify; first ray-finned fishes; plants and animals colonize land
Mass extinction at end of period (~75% of species lost)
Rapid diversification of multicellular animals; diverse photosynthetic protists
Origin of photosynthesis, multicellular organisms, and eukaryotes
Origin of life; prokaryotes flourish
Life not yet present

 Media Clip 24.1 The Age of the Earth www.Life11e.com/mc24.1

Radioisotopes provide a way to date fossils and rocks

Radioactive isotopes of atoms—***radioisotopes**—decay in a predictable pattern over long periods. Over a specific time interval, known as a **half-life**, half of the atoms in a radioisotope decay to become a different isotope (**Figure 24.1A**). The use of this knowledge to date fossils and rocks is known as **radiometric dating**.

- half-life** The time required for half of a sample of a radioactive isotope to decay to its stable, nonradioactive form, or for a drug or other substance to reach half its initial dosage.
- radiometric dating** A method for determining the age of objects such as fossils and rocks based on the decay rates of radioactive isotopes.

(B)

Radioisotope	Decay product	Half-life(years)	Useful dating range (years)
Carbon-14(¹⁴ C)	Nitrogen-14(¹⁴ N)	5,700	100-60,000
Uranium-	Thorium-	80,000	10,000-500,000

^{234}U	^{230}Th		
Uranium-235 (^{235}U)	Lead-207(^{207}Pb)	704 million	200,000-4.5 billion
Potassium-40 (^{40}K)	Argon-40(^{40}Ar)	1.3 billion	10 million-4.5 billion

Figure 24.1 Radioactive Isotopes Allow Us to Date Ancient Rocks The decay of radioactive isotopes into stable isotopes happens at a steady rate. A half-life is the time it takes for half of the remaining atoms to decay in this way. **(A)** The graph demonstrates the principle of half-life using carbon-14 (^{14}C) as an example. The half-life of ^{14}C is 5,700 years. **(B)** Different radioisotopes have different characteristic half-lives that allow us to estimate the ages of many rocks.

To use a radioisotope to date a past event, we must know or estimate the concentration of that isotope at the time of that event, and we must know the radioisotope's half-life. In the case of carbon-14, a radioisotope of carbon, the production of new carbon-14 (^{14}C) in the upper atmosphere—by the reaction of neutrons with nitrogen-14 ^{14}N , a stable isotope of nitrogen—just balances the natural radioactive decay of ^{14}C into ^{14}N . Therefore the ratio of ^{14}C to the more common stable isotope of carbon, carbon-12 (^{12}C), is relatively constant in living organisms and in their environment. As soon as an organism dies, however, it ceases to exchange carbon compounds with its environment. Its decaying ^{14}C is no longer replenished, and the ratio of ^{14}C to ^{12}C in its remains decreases over time. Paleontologists can use the ratio of ^{14}C to ^{12}C in fossil material to date fossils that are less than 60,000 years old (and thus the sedimentary rocks that contain those fossils). If fossils are older than that, so little ^{14}C remains that the limits of detection using this particular isotope are reached, and other radioisotopes must be used instead.

Radiometric dating methods have been expanded and refined

Sedimentary rocks are formed from materials that existed for varying lengths of time before being weathered, fragmented, and transported, sometimes over long distances, to the site of their deposition. Therefore the radioisotopes in sedimentary rocks do not contain reliable information about the date of their formation. Radiometric dating of rocks older than 60,000 years requires estimating radioisotope concentrations in [igneous rocks](#), which are formed when molten material cools. To date sedimentary strata, geologists search for places where volcanic ash or lava flows have intruded into the sedimentary rock.

igneous rocks Rocks solidified from lava or magma.

A preliminary estimate of the age of an igneous rock determines which radioisotopes can be used to date it ([Figure 24.1B](#)). The decay of potassium-40 (which has a half-life of 1.3 billion years) to argon-40, for example, has been used to date many of the ancient events in the evolution of life. Fossils in the adjacent sedimentary rock that are similar to those in other rocks of known ages provide additional clues to the rock's age.

Scientists have used several methods to construct a geological time scale

Radiometric dating of rocks, combined with fossil analysis, is the most powerful method of determining geological age. But in places where sedimentary rocks do not contain suitable

igneous intrusions and few fossils are present, paleontologists turn to other dating methods.

One method, known as paleomagnetic dating, relates the ages of rocks to patterns in Earth's magnetism, which change over time. Earth's magnetic field is not constant. Changes in both the strength and the polarity of Earth's magnetic field occur over time. Reversals of the poles occur periodically. Both sedimentary and igneous rocks preserve a record of Earth's magnetic field at the time they were formed, and that record can be used to determine the ages of those rocks. Other dating methods use information about continental drift, information about sea level changes, and ***molecular clocks**.

Using all of these methods, geologists developed the geological time scale (see [Table 24.1](#)). They divided the broad history of life into four eons. The Hadean eon refers to the time on Earth before life evolved. The early history of life occurred in the Archean eon, which ended about the time that photosynthetic organisms first appeared on Earth. Prokaryotic life diversified rapidly in the Proterozoic eon, and the first eukaryotes in the fossil record date from this time. These three eons are sometimes referred to collectively as Precambrian time, or simply the **Precambrian**. The Precambrian lasted for approximately 4 billion years and thus accounts for the vast majority of geological time. It was in the Phanerozoic eon, however—a mere 542-million-year time span—that multicellular eukaryotes rapidly diversified. To emphasize the events of the Phanerozoic, [Table 24.1](#) shows the subdivision of this eon into eras and periods. The boundaries between these divisions of time are based largely on the striking differences geologists observe in the assemblages of fossil organisms contained in successive strata. This geological record of life reveals a remarkable story of a world in which the continents and biological communities are constantly changing.

Precambrian The first and longest period of geological time, during which life originated.

24.1 recap

Fossils in sedimentary rock strata enabled geologists to determine the relative ages of organisms, but absolute dating was not possible until the discovery of radioactivity. Geologists divide the history of life into eons, eras, and periods, based on assemblages of fossil organisms found in successive layers of rocks.

learning outcomes

You should be able to:

- Design and interpret a geological map indicating the ages of exposed rocks.
- Suggest appropriate methods for dating fossils and rocks.

Imagine you have been asked to produce a geological map of volcanic rocks formed between 400 and 600 million years ago. You collect samples from ten sites, as indicated below, and determine the ratio of ^{206}Pb to ^{238}U for each site. Use the data below to answer the following questions.

Site	$^{206}\text{Pb}/^{238}\text{U}$ ratio	Estimated age (mya)
1	0.076	474
2	0.077	479
3	0.069	431
4	0.081	505
5	0.076	474
6	0.070	435
7	0.089	550
8	0.080	500
9	0.079	495
10	0.077	479

1. Assign each site to a geological period based on the information in this table and in [Table 24.1](#).
2. Mark rough boundaries between the sites using the estimated ages and geological periods of the samples.
3. If you wanted to refine the boundary between the Ordovician and Silurian periods on your map, which sampling site would you add to your analysis: x, y, or z?

As geologists began to develop accurate ways to measure the age of Earth, they began to understand that Earth is far older than anyone had previously understood. During its 4.5-billion-year history, Earth has undergone massive physical changes. These changes have influenced the evolution of life, and life, in its turn, has influenced Earth's physical environment.

***connect the concepts** As noted in [Key Concept 2.1](#), stable isotopes of the same element have the same number of protons but different numbers of neutrons. Radioisotopes, however, are not stable; they spontaneously give off energy in the form of alpha, beta, or gamma radiation, which transforms the original atom.

***connect the concepts** As [Key Concept 21.3](#) explains, a molecular clock measures the average rate at which a given gene or protein product accumulates changes, and this rate of change can be used to deduce the geological time when two biological lineages diverged from one another.

24.2 Changes in Earth's Physical Environment Have Affected the Evolution of Life

As we saw in the previous section, the Phanerozoic eon has been notable for the rapid diversification of multicellular eukaryotes. But the diversity of multicellular organisms has not simply increased steadily through time. New species have arisen, and species have gone extinct, throughout the history of life. In the absence of major, rapid environmental changes, the average rate of extinction is known as the background extinction rate. But there have been times during which extinction rates have increased dramatically over the background levels ([Figure 24.2](#)). These [mass extinction events](#) are the cause of some of the striking differences in fossil assemblages that geologists use to divide the Phanerozoic eon into eras and periods. After each mass extinction, the diversity of life rebounded, although recovery took millions of years. In this section we will discuss some of the physical changes on Earth that have resulted in dramatic changes in life's diversity.

Figure 24.2 Periodic Mass Extinctions Mark Many Geologic Boundaries Five sharp rises (marked by red dots) above the background extinction rate have occurred throughout the Phanerozoic. The most sweeping of these events, the end-Permian

extinction, was associated with dramatic drops in sea level (see [Figure 24.4](#)), global temperature, and atmospheric oxygen level (see [Figure 24.8](#)).

mass extinction event A period of evolutionary history during which rates of extinction are much higher than during intervening times.

focus your learning

The evolution of life has changed the physical nature of Earth.

The evolution of life and the physical nature of Earth are mutually related.

Research on living organisms can help us understand the evolution of ancient organisms.

Earth's continents and climates have changed over time

The globes and maps that adorn our walls, shelves, and books give an impression of a static Earth. It would be easy for us to assume that the continents have always been where they are. But we would be wrong. The idea that Earth's land masses have changed their positions over the millennia, and that they continue to do so, was first put forth in 1912 by the German meteorologist and geophysicist Alfred Wegener. His idea, known as [continental drift](#), was initially met with skepticism and resistance. By the 1960s, however, physical evidence and increased understanding of [plate tectonics](#)—the geophysics of the movement of major land masses—had convinced virtually all geologists of the reality of Wegener's vision. Plate tectonics provided the geological mechanism that explained Wegener's hypothesis of continental drift.

continental drift The gradual movements of the world's continents that have occurred over billions of years.

plate tectonics [Gk. *tekton*: builder] The scientific study of the structure and movements of Earth's lithospheric plates, which are the cause of continental drift.

Earth's crust consists of several solid plates, which collectively make up the solid [lithosphere](#) ("stone sphere"). Thick continental and thinner oceanic lithospheric plates overlie a viscous, malleable layer of Earth's mantle, known as the [asthenosphere](#) ("weak sphere"). Heat produced by radioactive decay deep in Earth's core sets up large-scale convection currents in the mantle. New crust is formed as mantle material rises between diverging plates, pushing them apart.

lithosphere (lith' o sphere) [Gk. *lithos*: strong] The crust of solid rock plates that overlays the viscous mantle of Earth. The movements of the lithosphere are the source of plate tectonics. (Contrast with asthenosphere.)

asthenosphere (ass thenn' o sphere) [Gk. *asthenes*: weak] The viscous, malleable (changeable) layer of Earth's mantle. It is overlain by the solid lithospheric plates.

Where oceanic plates and continental plates converge, the thinner oceanic plate is forced underneath the thicker continental plate, a process known as [subduction](#). Subduction results in volcanism and mountain building on the continental boundary (**Focus: Key** [Figure 24.3A](#)). For example, in the Pacific Northwest of North America, a series of volcanoes formed the Cascade

mountain range as the Juan de Fuca oceanic plate has been subducted beneath a portion of the continental North American Plate (**Focus: Key Figure 24.3B**). When two oceanic plates collide, one is subducted below the other, producing a deep oceanic trench and associated volcanic activity. The deepest part of the world's oceans—the Mariana Trench in the western Pacific—formed where two oceanic plates collided. Volcanic activity associated with the subduction at the Mariana Trench produced the nearby Mariana Islands.

subduction In plate tectonics, the movement of one lithospheric plate under another.

focus: key figure

Figure 24.3 Plate Tectonics and Continental Drift (A) The heat of Earth's core generates convection currents in the viscous mantle material underlying the oceanic

and continental plates. Those currents push the continental plates, along with the land masses they carry, together or apart. Where plates collide, one may slide under the other, creating mountain ranges and often volcanoes. **(B)** The Cascade Range of the Pacific Northwest of North America is an example of a mountain chain produced by subduction of an oceanic plate under a continental plate.

Q: Why are both shores of the Pacific Ocean ringed with volcanic mountain ranges?

Media Clip 24.2 **Lava Flows and Magma Explosions** www.Life11e.com/mc24.2

When two thick continental plates collide, neither plate is subducted. Instead, the plates push up against one another, forming high mountain chains. The highest mountain chain in the world, the Himalayas, was formed this way when the Indian Plate collided with the Eurasian Plate. When continental plates diverge, new crust forms in the intervening spaces, resulting in deep clefts called rift valleys in which large freshwater lakes typically form. The Great Rift Valley lakes of eastern Africa, including Lake Malawi (discussed at the opening of [Chapter 22](#)), were formed in this way. Two plates can also slide past one another, forming a transform fault boundary (such as the San Andreas Fault that produces violent seismic activity in parts of California).

Many physical conditions on Earth have oscillated in response to plate tectonic processes. We now know that the movement of the plates has sometimes brought continents together and at other times has pushed them apart, as seen in the maps across the top of [Figure 24.14](#). The positions and sizes of the continents influence oceanic circulation patterns, global climates, and sea levels. Sea level is influenced directly by plate tectonic processes (which can influence the depth of ocean basins) and indirectly by oceanic circulation patterns, which affect patterns of glaciation. As climates cool, glaciers form and tie up water over land masses; as climates warm, glaciers melt and release water.

Animation 24.1 **Movement of the Continents** www.Life11e.com/a24.1

Earth's climate has shifted between hot and cold conditions

Through much of Earth's history, the climate was considerably warmer than it is today, and temperatures decreased more gradually toward the poles. At other times, Earth was colder than it is today. Periodic rapid drops in sea level throughout the history of Earth have resulted mainly from increased global glaciation ([Figure 24.4](#)). Many of these drops in sea level were accompanied by mass extinctions—particularly of marine organisms, which could not survive the disappearance of the shallow seas that covered vast areas of the continental shelves.

Figure 24.4 Sea Levels Have Changed Repeatedly Rapid drops in sea level are

associated with periods of globally cooler temperatures and increased glaciation. Most mass extinctions of marine organisms have coincided with low sea levels.

Q: Why do cooler global temperatures result in lower sea levels?

Earth's cold periods were separated by long periods of milder climates. Because we are living in one of the colder periods, it is difficult for us to imagine the mild climates that were found at high latitudes during much of the history of life. The Quaternary period has been marked by a series of glacial advances, interspersed with warmer interglacial intervals during which the glaciers retreated.

"Weather" refers to the daily events at a given location, such as individual storms and the high and low temperatures on a given day. "Climate" refers to long-term average expectations over the various seasons at a given location. Weather often changes rapidly, whereas climates typically change slowly. However, major climatic shifts have taken place over periods as short as 5,000 to 10,000 years, primarily as a result of changes in Earth's orbit around the sun. A few climatic shifts have been even more rapid. For example, during one Quaternary interglacial period, the ice-locked Antarctic Ocean became nearly ice-free in less than 100 years. Some climate changes have been so rapid that the extinctions caused by them appear to be nearly instantaneous in the fossil record. Such rapid changes are usually caused by sudden shifts in ocean currents.

We are currently living in a time of ***rapid climate change** caused by a buildup of atmospheric CO₂, primarily from the burning of fossil fuels by human populations. We are reversing the energy transformations accrued in the burial and decomposition of organic material that occurred (especially) in the Carboniferous, Permian, and Triassic, which gave rise to the fossil fuels we are using today. But we are burning these fuels over a few hundred years, rather than the many millions of years over which those deposits accumulated. The current rate of increase in atmospheric CO₂ is unprecedented in Earth's history. A doubling of the atmospheric CO₂ concentration—which may happen during the current century—is expected to increase the average temperature of Earth, change rainfall patterns, melt glaciers and ice caps, and raise sea levels.

Volcanoes have occasionally changed the history of life

Most volcanic eruptions produce only local or short-lived effects, but a few large volcanic eruptions have had major consequences for life. When Krakatau (a volcanic island in the Sunda Strait off Indonesia) erupted in 1883, it ejected more than 25 cubic kilometers of ash and rock as well as large quantities of sulfur dioxide gas (SO₂). The SO₂ was ejected into the stratosphere and carried by high-altitude winds around the planet. Its presence led to high concentrations of sulfurous acid (H₂SO₃) in high-altitude clouds, creating a "parasol effect" that reduced the amount of sunlight reaching Earth's surface. Global temperatures dropped by 1.2°C in the year following the eruption, and global weather patterns showed strong effects for another 5 years. More recently, the eruption of Mount Pinatubo in the Philippines in 1991 ([Figure 24.5](#)) temporarily reduced global temperatures by about 0.5°C.

Figure 24.5 Volcanic Eruptions Can Cool Global Temperatures When Mount Pinatubo erupted in 1991, it increased the concentrations of sulfurous acid in high-altitude clouds, which temporarily lowered global temperatures by about 0.5°C .

Although these individual volcanoes had only relatively shortterm effects on global temperatures, they suggest that the simultaneous eruption of many volcanoes could have a much stronger effect on Earth's climate. What would cause many volcanoes to erupt at the same time? The collision of continents during the Permian period, about 275 million years ago (mya), formed a single, gigantic land mass and caused a multitude of massive volcanic eruptions as the continental plates overrode one another (see [Figure 24.3](#)). Emissions from these eruptions blocked considerable sunlight, contributing to the advance of glaciers and a consequent drop in sea level (see [Figure 24.4](#)). Thus volcanic eruptions were probably responsible, at least in part, for the greatest mass extinction in Earth's history.

Extraterrestrial events have triggered changes on Earth

At least 30 meteorites of sizes between tennis and soccer balls strike Earth each year. Collisions with larger meteorites or comets are rare, but such collisions have probably been responsible for several mass extinctions. Several types of evidence tell us about these collisions. Their craters, and the dramatically disfigured rocks that result from their impact, are found in many places. Geologists have discovered compounds in these rocks that contain helium and argon with isotope ratios characteristic of meteorites, which are very different from the ratios found elsewhere on Earth.

A meteorite caused or contributed to a mass extinction at the end of the Cretaceous period (about 65.5 mya). The first clue that a meteorite was responsible came from the abnormally high concentrations of the element iridium found in a thin layer separating rocks deposited during the Cretaceous from rocks deposited during the Tertiary ([Figure 24.6](#)). Iridium is abundant in some meteorites, but it is exceedingly rare on Earth's surface. When scientists discovered a circular crater 180 km in diameter buried beneath the northern coast of the Yucatán Peninsula of Mexico, they constructed the following scenario. When it collided with Earth, the meteorite released energy equivalent to that of 100 million megatons of high explosives, creating great tsunamis. A massive plume of debris rose into the atmosphere, spread around Earth, and descended. The descending debris heated the atmosphere to several hundred degrees and ignited massive fires. It also blocked the sun, preventing plants from photosynthesizing. The settling debris formed the iridium-rich layer. About a billion tons of soot with a composition matching that of smoke from forest fires were also deposited. These events had devastating

effects on biodiversity. Many fossil species (including non-avian dinosaurs) that are found in Cretaceous rocks are not found in the overlying Tertiary rocks.

Figure 24.6 Evidence of a Meteorite Impact The white layers of rock are Cretaceous in age, whereas the layers at the upper left were deposited in the Tertiary. Between the two is a thin, dark layer of clay that contains large amounts of iridium, a metal common in some meteorites but rare on Earth. Its high concentration in this sediment layer, deposited about 65.5 million years ago, suggests the impact of a large meteorite at that time.

Oxygen concentrations in Earth's atmosphere have changed over time

As the continents have moved over Earth's surface, the world has experienced other physical changes, including large increases and decreases in atmospheric oxygen concentrations. The atmosphere of early Earth probably contained little or no free oxygen gas (O_2). The increase in atmospheric O_2 came in two big steps more than a billion years apart.

The first step occurred at least 2.4 billion years ago (bya), when certain bacteria evolved the ability to use water as the source of hydrogen ions for photosynthesis. By chemically splitting H_2O , these bacteria generated O_2 as a waste product. They also made electrons available for reducing CO_2 to form the carbohydrate end-products of photosynthesis (see [Key Concept 10.3](#)). The O_2 they produced dissolved in water and reacted with dissolved iron. The reaction product then precipitated as iron oxide, which accumulated in alternating layers of red and dark rock known as banded iron formations ([Figure 24.7](#)). These formations provide evidence for the earliest photosynthetic organisms. As photosynthetic organisms continued to release O_2 , oxygen gas began to accumulate in the atmosphere.

Figure 24.7 Banded Iron Formations Indicate Early Photosynthesis The alternating red and dark layers in this 2.25-billion-year-old sedimentary rock formation from Lake Superior resulted from a reaction between dissolved iron and the atmospheric oxygen produced by Earth's first photosynthetic organisms. The chemical reaction produced nearly pure iron oxide, or hematite, which forms the gray, metallic layers in this sample. The red bands are jasper tinged with much smaller amounts of iron oxide.

The second step occurred about a billion years later, when some of these photosynthetic bacteria became symbiotic within eukaryote cells, leading to the evolution of chloroplasts in photosynthetic plants and other eukaryotes. This change resulted in continued accumulation of O_2 in Earth's atmosphere ([Figure 24.8](#)).

Figure 24.8 Atmospheric; Oxygen Concentrations Have Changed over Time

Changes in atmospheric oxygen concentrations have strongly influenced, and have been influenced by, the evolution of life. (Note that the horizontal axis of the graph is on a logarithmic scale.)

Q: Why did oxygen levels decrease at the end of the Permian?

One group of O_2 -generating bacteria, the cyanobacteria, were a major component of complex communities that formed rocklike structures called stromatolites, which are abundantly preserved in the fossil record. To this day, stromatolites are still formed in a few very salty places ([Figure 24.9](#)). Cyanobacteria liberated enough O_2 to open the way for the evolution of oxidation reactions as the energy source for the synthesis of ATP.

(A)

5 cm

(B)

Figure 24.9 Stromatolites (A) A vertical section through a fossil stromatolite. **(B)** These rocklike structures are living stromatolites that thrive in the very salty waters of Shark Bay in Western Australia.

Thus the evolution of life irrevocably changed the physical nature of Earth. Those physical changes, in turn, influenced the evolution of life. When it first appeared in the atmosphere, O_2 was toxic to most of the anaerobic prokaryotes that inhabited Earth at the time. Over millennia, however, prokaryotes that evolved the ability to tolerate and use O_2 not only survived but gained the advantage. Aerobic metabolism proceeds more rapidly, and harvests energy more efficiently, than anaerobic metabolism. Organisms with aerobic metabolism replaced anaerobes in most highly oxygenated environments.

An atmosphere rich in O_2 also made possible larger and more complex organisms. Small single-celled aquatic organisms can obtain enough oxygen by simple diffusion even when dissolved oxygen concentrations in the water are very low. Larger single-celled organisms, however, have lower surface area-to-volume ratios. To obtain enough oxygen by simple diffusion, larger organisms must live in an environment with a relatively high oxygen concentration. Bacteria can thrive at 1 percent of the current oxygen concentration, but eukaryotic cells require levels that are at least 2-3 percent of the current concentration. For concentrations of dissolved oxygen in the oceans to have reached these levels, much higher atmospheric concentrations were needed.

Probably because it took many millions of years for Earth to develop an oxygenated atmosphere, only single-celled prokaryotes lived on Earth for more than 2 billion years. About 1.5 bya, atmospheric O_2 concentrations became high enough for larger eukaryotic cells to flourish. Further increases in atmospheric O_2 concentrations in the late Precambrian enabled several groups of multicellular organisms to evolve (see [Figure 24.8](#)).

Oxygen concentrations increased again during the Carboniferous and Permian periods because of the evolution of large vascular plants. These plants lived in the expansive lowland swamps that existed at the time (see [Table 24.1](#)). Massive amounts of organic material were buried in these swamps as the plants died, leading to the formation of Earth's vast coal deposits. Because the buried organic material was not subject to oxidation as it decomposed, and because the living plants were producing large quantities of O_2 , atmospheric O_2 increased to concentrations that have not been reached again in Earth's history (see [Figure 24.8](#)). As mentioned at the opening of this chapter, these high concentrations of atmospheric O_2 allowed the evolution of giant flying insects and large amphibians that could not survive in today's atmosphere.

The drying of the lowland swamps at the end of the Permian reduced burial of organic matter as well as the production of O_2 , so atmospheric O_2 concentrations dropped rapidly. Over the past 200 million years, with the diversification of flowering plants, O_2 concentrations have again increased, but not to the levels that characterized the Carboniferous and Permian periods.

Biologists have conducted experiments revealing the changing selection pressures that can accompany changes in atmospheric O_2 concentrations. When fruit flies (*Drosophila*) are raised in hyperoxic conditions (i.e., with artificially increased atmospheric concentrations of O_2), they evolve larger body sizes in just a few generations (**Investigating Life: The Relationship between Atmospheric Oxygen Concentration and Body Size in Insects**). The present atmospheric O_2 concentrations appear to constrain body size in these flying insects, whereas increases in O_2 appear to relax those constraints. This experiment demonstrates that the ***stabilizing selection** on body size at current O_2 concentrations can quickly switch to **directional selection** for a change in body size in response to a change in O_2 concentrations.

▶ investigatinglife The Relationship between Atmospheric Oxygen Concentration and Body Size in Insects

experiment

Original Paper: Klok, C. J., A. J. Hubb and J. F. Harrison. 2009. Single and multigenerational responses of body mass to atmospheric oxygen concentration in *Drosophila melanogaster*: Evidence for roles of plasticity and evolution. *Journal of Evolutionary Biology* 22: 2496–2504.

C. Jaco Klok and his colleagues asked whether insects raised in hyperoxic conditions (i.e., in an atmosphere having a higher partial pressure of oxygen than is normal today) would evolve to be larger than their counterparts raised under today's atmospheric conditions. They raised strains of fruit flies (*Drosophila melanogaster*) under both conditions to test the effects of increased O_2 concentrations on the evolution of body size.

HYPOTHESIS ▶ In hyperoxic conditions, increased partial pressure of oxygen results in evolution of increased body size in flying insects.

METHOD

1. Separate a population of fruit flies into multiple lineages.
2. Raise half the lineages in current atmospheric (control) conditions; raise the other lineages in hyperoxic (experimental) conditions. Continue all lineages for seven generations.
3. Raise the F_8 individuals of all lineages under identical (current) atmospheric conditions.
4. Weigh 50 flies from each of the replicate lines and test for statistical differences in body weight.

RESULTS The average body mass of F_8 individuals of both sexes raised under hyperoxic conditions was significantly ($P < 0.001$) greater than that of individuals in the control lineages.

CONCLUSION ▶ Increased O_2 concentrations led to evolution of larger body size in fruit flies, consistent with the trends seen among other flying insects in the fossil record.

work with the data

Original Papers: Harrison, J. F. and G. G. Haddad. 2011. Effects of oxygen on growth and size: Synthesis of molecular, organismal and evolutionary studies with *Drosophila melanogaster*. *Annual Review of Physiology* 73: 13.1–13.9.

Harrison, J. F., A. Kaiser and J. M. VandenBrooks. 2010. Atmospheric oxygen level and the evolution of insect body size. *Proceedings of the Royal Society of London B* 277: 1937–1946.

The data in the bar graphs show that the body mass of individuals in the experimental populations of *Drosophila* increased, on average, about 2 percent per generation under hyperoxic conditions (although the rate of increase was not constant over the experiment). Here you will extrapolate from Harrison et al.'s study to determine whether the observed rate of increase in body mass per generation that these researchers observed in *Drosophila* is sufficient to account for the giant dragonflies of the Permian period.

QUESTIONS

1. Suppose that the average rate of increase in dragonfly size during the Permian was much slower than the rate observed in the experiment. For this exercise, assume that the actual rate of increase for dragonflies was just 0.01 percent per generation, rather than the 2 percent observed over a few generations for *Drosophila*. Also assume that dragonflies complete only 1 generation per year (as opposed to 40 or more generations for *Drosophila*). Starting with an average body mass of 1 gram, calculate the projected increase in dragonfly body mass over 50,000 years. This calculation is similar to computing compound interest for a savings account. Use the formula $W = S(1 + R)^N$ where W = the final mass, S = the starting mass, R = the rate of increase per generation (0.0001 in this case), and N = the number of generations.
2. What percent of the Permian period does 50,000 years represent? Use Table 24.1 for your calculation.
3. Given your calculations, do you think that increased O_2 concentrations during the Permian were sufficient to account for the evolution of giant dragonflies? Why or why not?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Extinction happens continuously, but mass extinctions result from sudden environmental changes

The physical and biological components of Earth's environment are constantly changing. As we saw in [Chapter 23](#), new species are constantly being generated. At the same time, some species decline to the point that they can no longer maintain viable populations and go extinct. Both speciation and extinction have been occurring throughout the history of life. Why do

species go extinct? Shortterm or long-term environmental fluctuations can make growth or reproduction difficult. As new species arise, they may outcompete existing species for food, space, or other resources. If a prey species goes extinct, predators that depend on the prey may decline or disappear as well.

As population sizes decrease, the probability of extinction accelerates. At any population size, there is variation in reproductive success, and a particular individual may fail to reproduce successfully. When population sizes are very small, such variation has a bigger influence. Low reproduction by a few individuals in a small population is likely to lead to loss of the population. The smaller the population, the larger the role that chance plays. Variation in reproductive rates is less likely to lead to extinction in large populations, where chance effects play a much smaller role.

Smaller populations can also have density-dependent disadvantages compared with larger populations—a phenomenon known as the **Allee effect**. Allee effects can occur, for example, from the inability of a small group to defend itself against predators, or from a decline in the ability of individuals to find mates. Small populations can also decline from the negative effects of inbreeding depression and genetic drift (see [Chapter 21](#)). These processes can result in loss of genetic variation, uncovering of deleterious alleles, and loss of beneficial alleles.

Allee effect An increase in the population growth rate (r) as the population density decreases.
--

An experiment on sea palms (a species of kelp) illustrates the relative influence of various factors on extinction probability as it relates to population size ([Figure 24.10](#)). Biologists experimentally established isolated populations of sea palms on intertidal rocky shores and examined their survivorship through time. At small population sizes, random demographic factors were most likely to lead to local extinction, whereas environmental fluctuations were much more likely to cause the extinction of larger populations.

experiment

Figure 24.10A What Factors Influence Extinction in Small Populations?

Original Paper: Wootton, J. T. and C. A. Pfister. 2013. Experimental separation of genetic and demographic factors on extinction risk in wild populations. *Ecology* 94: 2117–2123.

J. Timothy Wootton and Catherine Pfister established new, isolated populations of sea palms (a species of kelp, *Postelsia palmaeformis*) on exposed rocky shores of the northwestern United States. They then studied the probability of population extinct as a function of genetic structure and population size.

HYPOTHESIS Random variation in demographic events (individual births and deaths) will overwhelm genetic factors as contributions to short-term extinction probabilities in small populations. Extinction in larger populations will occur primarily from environmental fluctuation.

METHOD

1. Establish new isolated populations of *Postelsia palmaeformis* on rocky shorelines.

Establish three types of populations:

- a. Inbred populations (populations derived from a single individual)
- b. Control populations (populations established from multiple individuals from the same source population)
- c. Outbred populations (populations established from multiple individuals from different source populations)

2. After populations are established, thin populations to small ($N = 20$) or large ($N = 50$) size. Follow the populations through time, recording population size each spring.

RESULTS

In the smallest populations, random variation in births and deaths was by far the largest contributing factor to population extinction. Genetic effects had very little contribution to short-term extinction rates in this species. Allee effects were most evident in populations of 1–10 individuals. Above $N = 10$, almost all population extinction resulted from environmental fluctuations.

CONCLUSION Chance variation in births and deaths has the highest effect on extinction at the smallest population sizes. At larger population sizes, most local extinction results from fluctuation in the environment.

work with the data

Figure 24.10B What Factors Influence Extinction in Small Populations?

After establishing the experimental populations, the researchers counted the number of individuals present in each population each spring. They then recorded which populations were extant (still existing) or extinct in the following year. The table shows data for a few of the population sizes they examined:

Population size in previous year	Number of populations extant in following year	Number of populations extinct in following year
1–5	2	13
20	13	13
50	19	5
100–1,000	24	0

QUESTIONS

1. Draw a graph showing probability of extinction (y axis) as a function of population size (x axis) based on the data presented above. Use a log scale for the x axis. Draw a curve to approximate the relationship between probability of extinction and population size.
2. The graph you produced in Question 1 shows the extinction probability of a population after 1 year. If you started a population with 20 individuals, how likely do you think it would be to survive for 2 years? What additional data could you collect after 1 year to help answer this question?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

The five mass extinction events shown in [Figure 24.2](#) are notable because they suddenly increased the extinction rate and affected a large percentage of living organisms at the same time. In each case, rapid and extreme environmental changes caused many species to go extinct simultaneously.

24.2 recap

Physical conditions on Earth have changed dramatically over time. Changes in Earth's climate and sea levels have had major effects on biological evolution. Continental drift,

volcanic eruptions, and large meteorite strikes have contributed to major climate changes during Earth's history, and many of these climate shifts have resulted in mass extinction events. Changes in atmospheric concentrations of O₂ have also influenced the evolution of life, and the evolution of life has, in turn, affected the physical nature of the planet.

learning outcomes

You should be able to:

- Place important events in biological history onto a time line of Earth's history.
- Characterize the relative impact of weather events and climate changes on Earth's physical conditions.
- Explain how the production of atmospheric oxygen has affected Earth and its living organisms.
- Analyze the connections between a specific geological event or environmental change (e.g., fluctuations in ocean currents or sea levels, volcanic eruptions, meteorite strikes) and an evolutionary trend among living organisms.

-
1. Explain why an occasional major winter blizzard is irrelevant to discussions of global climate warming.
 2. Describe changes in the environment that may have favored the evolution of groups of multicellular organisms near the end of the Precambrian.

The many dramatic physical events in Earth's history have influenced the nature and timing of evolutionary changes among Earth's living organisms. We now will look more closely at some of the major events that characterize the history of life on Earth.

***connect the concepts** Today's rapid climate changes are having an enormous effect on populations of many living organisms, as discussed in [Key Concept 58.2](#).

***connect the concepts** Stabilizing selection resists change from a current state, whereas directional selection results in change away from the current state (see [Key Concept 20.4](#)).

24.3 Major Events in the Evolution of Life Can Be Read in the Fossil Record

How do we know how the physical changes described in the previous section affected the evolution of life? To reconstruct life's history, scientists rely heavily on the fossil record. As we have seen, geologists divided Earth's history into eons, eras, and periods based on distinct fossil assemblages (see [Table 24.1](#)). Biologists refer to the assemblage of all organisms of all kinds living at a particular time or place as a [biota](#). All of the plants living at a particular time or place are its [flora](#); all of the animals are its [fauna](#).

biota (bye oh' tah) All of the organisms— animals, plants, fungi, and microorganisms— found in a given area. (Contrast with flora, fauna.)

flora (flore' ah) All of the plants found in a given area. (Contrast with fauna.)

fauna (faw' nah) All the animals found in a given area. (Contrast with flora.)

focus your learning

Earth's history is divided into geological periods that are associated with major events in biological evolution.

Life's diversity has expanded and contracted many times over Earth's history.

About 300,000 species of fossil organisms have been described and named, and the number steadily grows. The number of named species, however, is only a tiny fraction of the species that have ever lived. We do not know how many species lived in the past, but we have ways of making reasonable estimates. Of the present-day biota, about 1.8 million species have been named. The actual number of living species is estimated to be at least 10 million, and possibly much higher, because many species have not yet been discovered and described by biologists. So the number of described fossil species is only about 3 percent of the estimated minimum number of living species. Life has existed on Earth for about 3.8 billion years. Many species last only a few million years before undergoing speciation or going extinct. From this we know that Earth's biota must have turned over many times during geological history. So the total number of species that have lived over evolutionary time must vastly exceed the number living today. Why have only about 300,000 of these tens of millions of species been described from fossils to date?

Several processes contribute to the paucity of fossils

Only a tiny fraction of organisms ever become fossils, and only a tiny fraction of fossils are ever discovered by paleontologists. Most organisms live and die in oxygen-rich environments, in which they quickly decompose. Organisms are not likely to become fossils unless they are transported by wind or water to sites that lack oxygen, where decomposition proceeds slowly. Furthermore, geological processes transform many rocks, destroying the fossils they contain, and many fossil-bearing rocks are deeply buried and inaccessible. Paleontologists have studied only a tiny fraction of the sites that contain fossils, although they find and describe many new

ones every year.

The fossil record is most complete for marine animals that had hard skeletons (which resist decomposition). Among the nine major animal groups with hard-shelled members, approximately 200,000 species have been described from fossils—roughly twice the number of living marine species in these same groups. Paleontologists lean heavily on these groups in their interpretations of the evolution of life. Arthropods are also relatively well represented in the fossil record because they are numerically abundant and have hard exoskeletons ([Figure 24.11](#)). The fossil record, though incomplete, is good enough to document clearly the factual history of the evolution of life.

Figure 24.11 Fossils in Amber Chunks of amber—fossilized tree resin—often contain detailed fossils such as this spider, which was preserved when it became trapped in the sticky resin.

By combining information about physical changes during Earth’s history with evidence from the fossil record, scientists have composed portraits of what Earth and its inhabitants may have looked like at different times. We know in general where the continents were and how life changed over time, but many of the details are poorly known, especially for events in the more remote past.

Precambrian life was small and aquatic

Life first appeared on Earth about 3.8 bya ([Figure 24.12](#)). The fossil record of organisms that lived prior to the Phanerozoic is fragmentary, but it is good enough to establish that the total number of species and individuals increased dramatically in the late Precambrian.

Figure 24.12 A Sense of Life’s Time The top timeline shows the 4.5-billion-year history of Earth. Most of this history is accounted for by the Precambrian, a 3.4-billion-year time span that saw the origin of life and the evolution of cells, photosynthesis,

and multicellularity. The final 600 million years are expanded in the bottom timeline and detailed in [Figure 24.14](#).

For most of its history, life was confined to the oceans, and all organisms were small. For more than 3 billion years, all organisms lived in shallow seas. These seas slowly began to teem with microscopic prokaryotes. After the first eukaryotes appeared about 1.5 billion years ago, during the Proterozoic, unicellular eukaryotes and small multicellular animals fed on the microorganisms. Small floating organisms, known collectively as [plankton](#), were strained from the water and eaten by slightly larger filter-feeding animals. Other animals ingested sediments on the sea-floor and digested the remains of organisms within them. But it still took nearly a billion years before eukaryotes began to diversify rapidly into the many different morphological forms that we know today.

plankton Aquatic organisms that float in the water column, dependent on currents and wind for movement. Plankton include many protists, some algae, and larval animals.

What limited the diversity of multicellular eukaryotes (in terms of their size and shape) for much of their early existence? It is likely that a combination of factors was responsible. We have already noted that O₂ levels increased throughout the Proterozoic, and it is likely that high atmospheric and dissolved O₂ concentrations were needed to support large multicellular organisms. In addition, geologic evidence points to a series of intensely cold periods during the late Proterozoic, which would have resulted in seas that were largely covered by ice and continents that were covered by glaciers. The “snowball Earth” hypothesis suggests that cold conditions confined life to warm places such as hot springs, deep thermal vents, and perhaps a few equatorial oceans that avoided ice cover. The last of these Proterozoic glaciations ended about 580 million years ago, just before several major radiations of multicellular eukaryotes appear in the fossil record ([Figure 24.13](#)). Many of the multicellular organisms known from the late Proterozoic and early Phanerozoic were very different from any animals living today and may be members of groups that left no living descendants.

Figure 24.13 Diversification of Multicellular Organisms: The Cambrian

“Explosion” Shortly after the end of Proterozoic glaciations (about 580 mya), several major radiations of multicellular organisms appear in the fossil record. **(A)** These microscopic fossils from the Doushantuo rock formation of China are the remains of tiny one-, two-, four-, and eight-celled stages of multicellular organisms. **(B)** Unusual soft-bodied marine invertebrates, unlike any animals alive at present, characterize the fossilized fauna preserved at Ediacara in southern Australia. **(C)** By the early Phanerozoic, fossilized faunas such as those preserved in Canada’s Burgess Shale include extinct representatives of some of the major animal groups alive today.

Life expanded rapidly during the Cambrian period

The Cambrian period (542-488 mya) marks the beginning of the Paleozoic, the first era of the Phanerozoic. The O_2 concentration in the Cambrian atmosphere was approaching its current level, and the glaciations of the late Proterozoic had ended nearly 40 million years earlier. A geologically rapid diversification of life took place that is often called the [Cambrian explosion](#). This name is somewhat misleading, as the series of radiations it refers to actually began before the start of the Cambrian and continued for about 60 million years into the early Cambrian (see [Figure 24.12](#)). Nonetheless, 60 million years represents a relatively short amount of time, especially considering that the first eukaryotes had appeared about a billion (= 1,000 million) years earlier. Many of the major animal groups represented by species alive today first appeared during these evolutionary radiations. [Figure 24.14](#) provides an overview of the numerous continental and biotic innovations that have characterized the Phanerozoic.

Cambrian explosion The rapid diversification of multicellular life that took place during the Cambrian period.

Figure 24.14 A Brief History of Multicellular Life on Earth The geologically rapid “explosion” of life shortly before and during the Cambrian saw the rise of many major animal groups that have representatives surviving today. The following three pages depict life’s history through the Phanerozoic. The movements of the major continents during the past half-billion years are shown in the maps of Earth, and associated biotas for each time period are depicted. The artists’ reconstructions are based on fossils such as those shown in the photographs.

For the most part, fossils tell us only about the hard parts of organisms, but in some well-studied Cambrian fossil beds the soft parts of many animals were preserved. Multicellular life was largely or completely aquatic during the Cambrian. If there was life on land at this time, it was probably restricted to microorganisms.

Many groups of organisms that arose during the Cambrian later diversified

Geologists divide the remainder of the Paleozoic era into the Ordovician, Silurian, Devonian, Carboniferous, and Permian periods. Each period is characterized by the diversification of

specific groups of organisms. Mass extinctions marked the ends of the Ordovician, Devonian, and Permian.

THE ORDOVICIAN (488-444 MYA)

During the Ordovician period, the continents, which were located primarily in the Southern Hemisphere, still lacked multicellular life. Evolutionary radiation of marine organisms was spectacular during the early Ordovician, especially among animals, such as brachiopods and mollusks, that lived on the seafloor and filtered small prey from the water. At the end of the Ordovician, as massive glaciers formed over the southern continents, sea levels dropped about 50 meters, and ocean temperatures dropped. About 75 percent of all animal species became extinct, probably because of these major environmental changes.

THE SILURIAN (444-416 MYA)

During the Silurian period, the continents began to merge together. Marine life rebounded from the mass extinction at the end of the Ordovician. Animals able to swim in open water and feed above the ocean floor appeared for the first time. Jawless fishes diversified, and the first fishes with supporting rays in their fins appeared. The tropical sea was uninterrupted by land barriers, and most marine organisms were widely distributed. On land, the first vascular plants evolved late in the Silurian (about 420 mya). The first terrestrial arthropods—scorpions and millipedes—evolved at about the same time.

THE DEVONIAN (416-359 MYA)

Rates of evolutionary change accelerated in many groups of organisms during the Devonian period. The major land masses continued to move slowly toward each other. In the oceans there were great evolutionary radiations of corals and of shelled, squidlike cephalopod mollusks. Fishes diversified as jawed forms replaced jawless ones and as bony armor gave way to the less rigid scales of modern fishes.

Terrestrial communities changed dramatically during the Devonian. Club mosses, horsetails, and tree ferns became common, and some attained the size of large trees. Their roots accelerated the weathering of rocks, resulting in the development of the first forest soils. The first plants to produce seeds appeared in the Devonian. The earliest fossil centipedes, spiders, mites, and insects date to this period, as do the earliest terrestrial vertebrates.

A massive extinction of about 75 percent of all marine species marked the end of the Devonian. Paleontologists are uncertain about its cause, but two large meteorites that collided with Earth at about that time (one in present-day Nevada, the other in Western Australia) may have been responsible, or at least a contributing factor. The continued merging of the continents, with the corresponding reduction in the area of continental shelves, may have also contributed to this mass extinction.

THE CARBONIFEROUS (359-299 MYA)

Large glaciers formed over high-latitude portions of the southern land masses during the Carboniferous period, but extensive swamp forests grew on the tropical continents. These forests were dominated by giant tree ferns and horsetails with small leaves. Their fossilized remains formed the coal we now mine for energy. In the seas, crinoids (a group of echinoderms, related to sea stars and sea urchins) reached their greatest diversity, forming “meadows” on the seafloor.

The diversity of terrestrial animals increased greatly during the Carboniferous. Snails, scorpions, centipedes, and insects were abundant and diverse. Insects evolved wings, becoming the first animals to fly. Flight gave herbivorous insects easy access to tall plants, and plant fossils from this period show evidence of chewing by insects ([Figure 24.15](#)). The terrestrial vertebrates split into two lineages. The amphibians became larger and better adapted to terrestrial existence, while the sister lineage led to the amniotes: vertebrates with well-protected eggs that can be laid in dry places.

THE PERMIAN (299-251 MYA)

During the Permian period, the continents merged into a single supercontinent called Pangaea. Permian rocks contain representatives of many of the major groups of insects we know today. By the end of the period the amniotes had split into two lineages: the reptiles, and a second lineage that would lead to the mammals. Ray-finned fishes became common in the freshwaters of Pangaea.

Toward the end of the Permian, conditions for life deteriorated. Massive volcanic eruptions resulted in outpourings of lava that covered large areas of Earth. The ash and gases produced by the volcanoes blocked sunlight and cooled the climate. The death and decay of the massive Permian forests rapidly used up atmospheric oxygen, and the loss of photosynthetic organisms meant that relatively little new atmospheric oxygen was produced. In addition, much of Pangaea was located close to the South Pole by the end of the Permian. All of these factors combined to produce the most extensive continental glaciers since the "snowball Earth" times of the late Proterozoic. Atmospheric oxygen concentrations gradually dropped from about 30 percent to 15 percent. At such low concentrations, most animals would have been unable to survive at elevations above 500 meters, so about half of the land area would have been uninhabitable at the end of the Permian. The combination of these changes resulted in the most drastic mass

extinction in Earth's history. Scientists estimate that about 96 percent of all multicellular species became extinct at the end of the Permian.

Geographic differentiation increased during the Mesozoic era

The few organisms that survived the Permian mass extinction found themselves in a relatively empty world at the start of the Mesozoic era (251 mya). As Pangaea slowly began to break apart in the Mesozoic, the biotas of the newly separated continents began to diverge. The oceans rose and once again flooded the continental shelves, forming huge, shallow inland seas. Atmospheric oxygen concentrations gradually rose. Life once again proliferated and diversified, but different groups of organisms came to the fore. The three groups of phytoplankton (floating photosynthetic organisms) that dominate today's oceans—dinoflagellates, coccolithophores, and diatoms—became ecologically important at this time, and their remains are the primary origin of the world's oil deposits. Seed-bearing plants replaced the trees that had ruled the Permian forests.

The Mesozoic era is divided into three periods: the Triassic, Jurassic, and Cretaceous. The Triassic and Cretaceous were terminated by mass extinctions, probably caused by meteorite impacts.

THE TRIASSIC (251-201.6 MYA)

Pangaea remained largely intact through the Triassic. Many invertebrate groups diversified, and many burrowing animals evolved from groups living on the surfaces of seafloor sediments. On land, conifers and seed ferns were the dominant trees. The first frogs and turtles appeared. A great radiation of reptiles began, which eventually gave rise to crocodilians and dinosaurs (including birds). The end of the Triassic was marked by a mass extinction that eliminated about 65 percent of the species on Earth.

THE JURASSIC (201.6-145.5 MYA)

Late in the Jurassic period, Pangaea became fully divided into two large continents: [Laurasia](#), which drifted northward, and [Gondwana](#) in the south. Ray-finned fishes rapidly diversified in the oceans. The first lizards appeared, and flying reptiles (pterosaurs) evolved. Most of the large terrestrial predators and herbivores of the period were dinosaurs. Several groups of mammals made their first appearance, and the earliest known fossils of flowering plants are from late in this period.

Laurasia The northernmost of the two large continents produced by the breakup of Pangaea.

Gondwana The large southern land mass that existed from the Cambrian (540 mya) to the Jurassic (138 mya). Present-day remnants are South America, Africa, India, Australia, and Antarctica.

THE CRETACEOUS (145.5-65.5 MYA)

By the mid-Cretaceous, Laurasia and Gondwana had largely broken apart into the continents we know today (although the Indian subcontinent was still separated from Asia). A continuous sea encircled the tropics. Sea levels were high, and Earth was warm and humid. Life proliferated both on land and in the oceans. Marine invertebrates increased in diversity. On land, the reptile radiation continued as dinosaurs diversified further and the first snakes appeared. Early in the Cretaceous, flowering plants began the radiation that led to their current dominance of the land. By the end of the period, many groups of mammals had appeared.

As described in [Key Concept 24.2](#), another meteorite-caused mass extinction took place at the end of the Cretaceous. In the seas, many planktonic organisms and bottom-dwelling

invertebrates became extinct. On land, almost all animals larger than about 25 kg in body weight became extinct. Many species of insects died out, perhaps because the growth of their food plants was greatly reduced following the impact. Some species in northern North America and Eurasia survived in areas that were not subjected to the devastating fires that engulfed most low-latitude regions.

Modern biotas evolved during the Cenozoic era

By the early Cenozoic era (65.5 mya), the positions of the continents were getting closer to their present positions, but the Indian subcontinent was still separated from Asia, and the Atlantic Ocean was much narrower. The Cenozoic was characterized by an extensive radiation of mammals, but other groups were also undergoing important changes.

Flowering plants diversified extensively and came to dominate world forests except in the coolest regions, where the forests were composed primarily of gymnosperms. Mutations of two genes in one group of plants (the legumes) allowed them to use atmospheric nitrogen directly by forming symbioses with a few species of nitrogen-fixing bacteria. The evolution of this symbiosis was the first “green revolution” and dramatically increased the amount of nitrogen available for terrestrial plant growth. This symbiosis remains fundamental to the ecological base of life as we know it today.

The Cenozoic era is divided into the Tertiary and the Quaternary periods, which are commonly subdivided into [epochs](#) ([Table 24.2](#)).

epoch A subdivision of a period in a geological time scale.

table 24.2 Subdivisions of the Cenozoic Era

Period	Epoch	Onset (mya)
Quaternary	Holocene (Recent)	0.01 (~10,000 years ago)
	Pleistocene	2.6
Tertiary	Pliocene	5.3
	Miocene	23
	Oligocene	34
	Eocene	55.8
	Paleocene	65.5

THE TERTIARY (65.5-2.6 MYA)

During the Tertiary period, the Indian subcontinent continued its northward drift. By about 55 mya it made initial contact with parts of southeastern Asia. By about 35 mya, the Indian Plate ran fully into the Eurasian Plate, and the Himalaya Mountains began to be pushed up as a result.

The early Tertiary was a hot and humid time, and the ranges of many plants shifted latitudinally. The tropics were probably too hot to support rainforest vegetation and instead were clothed in low-lying vegetation. In the middle of the Tertiary, however, Earth’s climate became considerably cooler and drier. Many lineages of flowering plants evolved herbaceous (nonwoody) forms, and grasslands spread over much of Earth.

By the start of the Cenozoic era, invertebrate faunas had already come to resemble those of today. It is among the terrestrial vertebrates that evolutionary changes during the Tertiary were most rapid. Frogs, snakes, lizards, birds, and mammals all underwent extensive radiations during the Tertiary. Three waves of mammals dispersed from Asia to North America across one

of the several land bridges that have intermittently connected the two continents during the past 55 million years. Rodents, marsupials, primates, and hoofed mammals appeared in North America for the first time.

THE QUATERNARY (2.6 MYA TO PRESENT)

We are living in the Quaternary period. It is subdivided into two epochs, the Pleistocene and the Holocene (the Holocene is also known as the Recent).

The Pleistocene was a time of drastic cooling and climate fluctuations. During 4 major and about 20 minor “ice ages,” massive glaciers spread across the continents, and the ranges of animal and plant populations shifted toward the equator. The last of these glaciers retreated from temperate latitudes less than 15,000 years ago. Organisms are still adjusting to this change. Many high-latitude ecological communities have occupied their current locations for no more than a few thousand years.

It was during the Pleistocene that divergence within one group of mammals, the primates, resulted in the evolution of the hominoid lineage. Subsequent hominoid radiation eventually led to the species *Homo sapiens*—modern humans. Many large bird and mammal species became extinct in Australia and in the Americas when *H. sapiens* arrived on those continents about 45,000 and 15,000 years ago, respectively. Many paleontologists believe at least some of these extinctions were the result of hunting and other influences of *Homo sapiens*.

The tree of life is used to reconstruct evolutionary events

The fossil record reveals broad patterns in life’s evolution. To reconstruct major events in the history of life, biologists also rely on the phylogenetic information in the tree of life (see [Appendix A](#)). We can use phylogeny, in combination with the fossil record, to reconstruct the timing of such major events as the acquisition of mitochondria in the ancestral eukaryotic cell, the several independent origins of multicellular organisms, and the movement of life onto dry land. We can also follow major changes in the genomes of organisms, and we can even reconstruct many gene sequences of species that are long extinct, as described in [Key Concept 21.3](#).

Changes in Earth’s physical environment have clearly influenced the diversity of organisms we see on the planet today. To study the evolution of that diversity, biologists examine the evolutionary relationships among species. Deciphering phylogenetic relationships is an important step in understanding how life has diversified on Earth. The next part of this book will explore the major groups of life and the different solutions these groups have evolved to meet major challenges such as reproduction, energy acquisition, dispersal, and escape from predation.

24.3 recap

Life evolved in the oceans about 3.8 billion years ago. It diversified as atmospheric oxygen approached its current level. Numerous climate changes and rearrangements of the continents, as well as meteorite impacts, contributed to five major mass extinctions.

learning outcomes

You should be able to:

- Explain how increases and decreases in biodiversity through time relate to major changes in Earth’s environmental conditions.
- Characterize environmental conditions during successive geological periods and connect these periods with major events in biological evolution.
- Illustrate the relationship between a phylogenetic tree and geological time.

1. Give a likely reason for the “green revolution” of the Cenozoic era, and explain why it enabled flowering plants to diversify.
2. Compare the tree of life in [Appendix A](#) with the chronology of major events in [Table 24.1](#). To represent the diversity of life in one figure, the tree in the appendix is not drawn proportionally in relation to time. Which geological eon, era, or period seems most distorted, and why? What major changes to the tree would be needed to show divergences in groups that are proportional?

investigatinglife

QA How can modern experiments test hypotheses about the evolutionary impact of ancient environmental changes?

Several experiments have been conducted to test the link between O₂ concentrations and evolution of body size in flying insects (one of these is discussed in Investigating Life: The Relationship between Atmospheric Oxygen Concentration and Body Size in Insects). Results of these experiments are consistent with the evolution of larger body size in flying insects in hyperoxic (high-oxygen) environments. Experiments have also been conducted under hypoxic (low-oxygen) conditions, such as existed at the end of the Permian. Results of these experiments suggest that the evolution of body size is constrained under hypoxic conditions, even under strong artificial selection for larger body size. These latter results are consistent with the extinction of many of the large flying insects at the end of the Permian, the result of rapidly decreasing O₂ concentrations. Giant flying insects simply could not have survived the lower O₂ concentrations that existed at that time. The mass extinction at the end of the Permian is the only known mass extinction that involved considerable loss of insect diversity.

Future directions

Experiments with living organisms are providing information about how quickly various groups of organisms evolve. They also inform us about the factors involved in extinction of species (as in the example in [Figure 24.10](#)). As human activities affect the climate of Earth, experimental approaches will be important to help us predict how our actions may affect future directions of evolution and extinction.

► 24.1 Events in Earth's History Can Be Dated

- The dates of evolutionary events can be determined by the dating of fossils and the **strata** of [sedimentary rocks](#) in which the fossils are found.

sedimentary rock Rock formed by the accumulation of sediment grains on the bottom of a body of water. Often contain stratified fossils that allow geologists and biologists to date evolutionary events relative to each other.

- [Radiometric dating](#) techniques use a variety of radioisotopes with different **half-lives** to date events at different times in the remote past. **Review Figure 24.1**

radiometric dating A method for determining the age of objects such as fossils and rocks based on the decay rates of radioactive isotopes.

- Geologists divide the history of life into eons, eras, and periods. These divisions are based largely on major differences in the fossil assemblages found in successive strata. Review [Table 24.1](#)

► 24.2 Changes in Earth's Physical Environment Have Affected the Evolution of Life

- Earth's crust consists of solid lithospheric plates that float on the viscous mantle. Continental drift is caused by convection currents in the mantle, which move the plates and the continents that lie on top of them. **Review Focus: Key Figure 24.3, Animation 24.1**
- Five episodes of [mass extinction events](#) punctuated the history of life in the Paleozoic and Mesozoic eras. **Review Figure 24.2**

mass extinction event A period of evolutionary history during which rates of extinction are much higher than during intervening times.

- Major physical events on Earth, such as continental collisions and volcanic eruptions, have affected Earth's surface, climate, atmosphere, and sea levels. In addition, extraterrestrial events such as meteorite strikes have created sudden and dramatic environmental shifts. All of these changes affected the history of life. **Review Figure 24.4**
- Oxygen-generating cyanobacteria liberated enough O₂ to open the door to oxidation reactions in metabolic pathways. Aerobic prokaryotes were able to harvest more energy than anaerobic organisms and began to proliferate. Increases in atmospheric O₂ concentrations supported the evolution of large eukaryotic cells and, eventually, multicellular organisms. **Review Figure 24.8, Investigating Life: The Relationship between Atmospheric Oxygen Concentration and Body Size in Insects**
- Extinctions of species happen throughout evolutionary history, but major, rapid

environmental changes can produce mass extinctions of many species simultaneously.

Review [Figure 24.10](#)

▶ 24.3 Major Events in the Evolution of Life Can Be Read in the Fossil Record

- Paleontologists use fossils and evidence of geological changes to determine what Earth and its biota may have looked like at different times. **Review** [Figure 24.12](#)
- Before the Phanerozoic, life was almost completely confined to the oceans. Multicellular life diversified extensively during the [Cambrian explosion](#), an example of an evolutionary radiation. **Review** [Figure 24.13](#)

Cambrian explosion The rapid diversification of multicellular life that took place during the Cambrian period.

- The periods of the Paleozoic era were each characterized by the diversification of specific groups of organisms. The Paleozoic ended with the most drastic mass extinction in Earth's history. During the Mesozoic era, distinct terrestrial biotas evolved on each continent. **Review** [Figure 24.14](#)
- Earth's [flora](#) has been dominated by flowering plants since the Cenozoic era began.

flora (flore' ah) All of the plants found in a given area. (Contrast with fauna.)

- The tree of life can be used to reconstruct the timing of evolutionary events.

► Apply What You've Learned

Review

4.1 Geologists use several methods to date ancient events.

4.3 Earth's history is divided into geological periods that are associated with major events in biological evolution.

The diagram below summarizes evidence gathered through the study of fossils and rocks from locations around the world. Assemblages of two groups of animal fossils are indicated as the Ediacaran biota and the Cambrian-type shelly biota.

The Ediacaran biota represents the remains of the oldest large multicellular animals in Earth's history. These were soft-bodied marine animals that lacked skeletons and attached to the sea floor by a holdfast or foot. With body shapes resembling modern ferns, they grew up to 1 meter in length.

Ediacaran animals appear to have flourished for at least 23 million years (as indicated in the diagram) before going extinct. They were followed by the Cambrian-type shelly biota, which had mineralized exoskeletons and were also complex, multicellular animals.

Questions

1. How would the geological strata in which Ediacaran fossils were discovered compare with those in which Cambrian-type shelly biota fossils were discovered? Justify your answer with evidence from the diagram.
2. What factors were likely to have favored the success of the Ediacaran biota at that time in Earth's history, but not earlier?
3. What factors could have resulted in the extinction of the Ediacaran biota and the rise of the Cambrian-type shelly biota?
4. It has been stated that "absence of evidence is not evidence of absence" in reference to the interpretation of the fossil record. Evaluate this statement as it relates to the study of the Ediacaran biota.
5. An index fossil is one whose presence in a geological formation can indicate the age of the formation. Propose a scenario to illustrate how Ediacaran fossils might be used as index fossils. Explain your

reasoning.

Bacteria Light Up the Sea

One night in January of 1995, the British merchant vessel *Lima* was off the coast of Somalia, near the Horn of Africa. This area is infamous for bands of pirates, so the crew was keeping a watchful eye on the seas when they spotted an eerie, whitish glow on the horizon. It was directly in their path, and there was no way to avoid it. Was this strange sight the result of some strange trick of piracy?

Within 15 minutes of first sighting the glow, the *Lima* was surrounded by shining waters for as far as her crew could see. The ship's log recorded that "it appeared as though the ship was sailing over a field of snow or gliding over the clouds." Fortunately for the crew, the glow had nothing to do with pirates.

For centuries, mariners in this part of the world had reported occasional "milky seas" in which the sea surface produced a strange glow at night, extending from horizon to horizon. Scientists up to that point had never been able to confirm the reality or the cause of such phenomena. It was well established, however, that many organisms emit light by bioluminescence, a complex, enzyme-catalyzed biochemical reaction that emits light but not heat.

What kind of organism could cause the vast expanse of bioluminescence observed by the *Lima*? Some marine organisms emit flashes of light when they are disturbed, but they could not have produced the sustained and uniform glow seen in milky seas. The only organisms known to produce the level of sustained bioluminescence consistent with milky seas are certain prokaryotes, such as bacteria of the genus *Vibrio*. Using information supplied by the *Lima*, biologists scanned satellite images of the Indian Ocean for the specific light wavelengths emitted by *Vibrio*. The satellite images clearly identified thousands of square kilometers of *Vibrio*-produced milky seas.

Vibrio's bioluminescence requires a critical concentration of a specific chemical signal produced by the bacteria, so at low densities, free-living *Vibrio* populations do not glow. But as a colony establishes itself on phytoplankton, the bacteria's population density increases and concentrations of the luminescence signal build up. Eventually bacterial density becomes high enough for the huge colony to produce visible light. Such chemical-induced action among bacterial cells is referred to as quorum sensing.

QA How and why do bacteria communicate with one another?

25.1 Bacteria and Archaea Are the Two Primary Divisions of Life

You may think that you have little in common with a bacterium. But all multicellular eukaryotes—including you—share many attributes with organisms that lack a nucleus, which are called **prokaryotes**. For example, all organisms, whether eukaryotes or prokaryotes,

prokaryotes Unicellular organisms that do not have nuclei or other membrane-enclosed organelles. Includes Bacteria and Archaea. (Contrast with eukaryotes.)

have cell membranes and ribosomes (see [Chapters 5](#) and [6](#)).

have a common set of metabolic pathways, such as glycolysis (see [Chapters 8](#) and [9](#)).

replicate DNA semiconservatively (see [Chapter 13](#)).

use DNA as the genetic material to encode proteins, and use similar genetic codes to produce those proteins by transcription and translation (see [Chapter 14](#)).

These shared features support the conclusion that all living organisms share a common ancestor. If life had multiple origins, there would be little reason to expect all organisms to use overwhelmingly similar genetic codes or to share structures as distinctive as ribosomes. Furthermore, similarities in the DNA sequences of genes that are shared by all organisms confirm the monophyly of life.

focus your learning

Bacteria and prokaryotic archaea share some features and differ in others.

Some groups of bacteria can be distinguished based on the Gram stain.

Lateral gene transfer can lead to discordant gene trees.

Although all living things share many features, major differences have evolved across the diversity of life. Biologists have now sequenced the genomes of many living organisms, and these genomes allow us to reconstruct the details of evolutionary history. These studies clarify that there are two fundamental divisions of life: Bacteria and Archaea ([Figure 25.1](#)). Another major group evolved from within the Archaea: the Eukarya, which includes all plants, animals, and fungi.

When biologists speak of three major **domains** of life, they usually mean Bacteria, prokaryotic Archaea, and Eukarya. But if you examine [Figure 25.1](#), you will see that eukaryotes evolved from within the prokaryotic Archaea. So in this sense, eukaryotes are a specialized group of Archaea that developed some important new features (including a cell nucleus) that allowed them to thrive. We call all the organisms that lack these specializations prokaryotes (Greek, “before the kernel,” or before the evolution of a cellular nucleus). Prokaryotes are clearly not all most closely related to one another, but the name “prokaryotes” is nonetheless a useful way of talking about all organisms that are not eukaryotes. In a similar manner, when most biologists talk about “archaea,” typically they are referring to just the prokaryotic Archaea.

domain (1) An independent structural element within a protein. Encoded by recognizable nucleotide sequences, a domain often folds separately from the rest of the protein. Similar domains can appear in a variety of different proteins across phylogenetic groups (e.g., “homeobox domain,” “calcium-binding domain”). (2) In phylogenetics, the three monophyletic branches of life (Bacteria, Archaea, and Eukarya).

Figure 25.1 The Major Groups of the Living World This phylogenetic tree of Bacteria and Archaea shows their relationships to each other and to Eukarya. The relationships among the many clades of bacteria, not all of which are listed here, are incompletely resolved at this time.

 Animation 25.1 **The Evolution of the Three Domains** www.Life11e.com/a25.1

All prokaryotic organisms are unicellular, although they may form large, coordinated colonies or communities consisting of many individuals. Eukaryotes, by contrast, include both unicellular as well as many multicellular life forms. As we saw in [Chapter 5](#), prokaryotic cells differ from eukaryotic cells in some important ways:

Prokaryotic cells do not divide by mitosis. Instead, after replicating their DNA, prokaryotic cells divide by their own method, binary fission (see [Key Concept 11.1](#)).

The organization of the genetic material differs. The DNA of the prokaryotic cell is not organized within a membrane-enclosed nucleus. DNA molecules in prokaryotes are often circular. Many (but not all) prokaryotes have only one main chromosome and are effectively haploid, although many have additional smaller DNA molecules, called plasmids (see [Key Concept 12.6](#)).

Prokaryotes have none of the membrane-enclosed cytoplasmic organelles that are found in most eukaryotes. However, the cytoplasm of a prokaryotic cell may contain a variety of infoldings of the cell membrane and photosynthetic membrane systems that are not found in eukaryotes.

Although the study and classification of eukaryotic organisms goes back centuries, much of our knowledge of the evolutionary relationships of prokaryotes is extremely recent. Not until the final quarter of the twentieth century did advances in molecular genetics and biochemistry enable the research that revealed the deep-seated distinctions between prokaryotic archaea and bacteria.

The two prokaryotic domains differ in significant ways

A glance at [Table 25.1](#) will show you that there are major differences (most of which cannot be seen even under an electron microscope) between the two prokaryotic domains. Prokaryotic archaea share a number of features with their relatives the eukaryotes, but they also retain some ancestral similarities with bacteria. (Note that we use lowercase when referring to members of these domains and initial capitals when referring to the domains themselves.) The basic unit of an archaeon (the term for a single archaeal organism) or bacterium (a single bacterial organism) is the prokaryotic cell. Each single-celled prokaryote contains a full complement of genetic and protein-synthesizing systems, including DNA, RNA, and all the enzymes needed to transcribe and translate genetic information into proteins. The prokaryotic cell also contains at least one system for generating the ATP it needs.

table 25.1 The Three “Domains” of Life			
Characteristic	Domain		
	Bacteria	Prokaryotic Archaea	Eukarya
Membrane-enclosed nucleus	Absent	Absent	Present
Membrane-enclosed organelles	Few	Absent	Many
Peptidoglycan in cell wall	Present	Absent	Absent
Membrane lipids	Ester-linked	Ether-linked	Ester-linked
	Unbranched	Branched	Unbranched
Ribosomes ^a	70S	70S	80S
Initiator tRNA	Formylmethionine	Methionine	Methionine
Operons	yes	Yes	Rare
Plasmids	Yes	Yes	Rare
Number of RNA polymerases ^b	One	One	Three
Ribosomes sensitive to chloramphenicol and streptomycin	Yes	No	No
Ribosomes sensitive to diphtheria toxin	No	Yes	Yes

^a70S ribosomes are smaller than 80S ribosomes.

^bThe structure of prokaryotic archaeal RNA polymerase is similar to that of eukaryotic polymerases.

Genetic studies clearly indicate that all forms of life share a single common ancestor. As we noted earlier, eukaryotes share a more recent common ancestor with certain groups of prokaryotic archaea than they do with bacteria (see [Figure 25.1](#)). However, the ***mitochondria** of eukaryotes and the **chloroplasts** of photosynthetic eukaryotes (such as plants) originated through endosymbiosis with bacteria. Some biologists prefer to view the origin of eukaryotes as a fusion of two equal partners (one ancestor that was related to modern prokaryotic archaea and another that was more closely related to modern bacteria). Others view the divergence of the early eukaryotes from specific groups of prokaryotic archaea as an event separate from and earlier than the later endosymbioses. In either case, most eukaryote genes are more closely related to those of specific groups of prokaryotic archaea, whereas other genes (especially genes related to mitochondria and chloroplasts) are most closely related to those of bacteria. The tree of life therefore contains some merging of lineages as well as the predominant divergence of lineages.

chloroplast [Gk. *kloros*: green + *plast*: a particle] An organelle bounded by a double membrane containing the enzymes and pigments that perform photosynthesis. Chloroplasts occur only in eukaryotes.

(A)

Gram-positive bacteria have a uniformly dense cell wall consisting primarily of peptidoglycan.

5 μm

(B)

Gram-negative bacteria have a very thin peptidoglycan layer and an outer membrane, which together make up the cell envelope.

Figure 25.2 The Gram Stain and the Bacterial Cell Wall When treated with Gram-staining reagents, the cell walls of bacteria react in one of two ways. **(A)** Gram-positive bacteria have a thick peptidoglycan cell wall that retains the violet dye and appears deep blue or purple. **(B)** Gram-negative bacteria have a thin peptidoglycan layer that does not retain the violet dye, but picks up the counterstain and appears pink to red.

 Activity 25.1 **Gram Stain and Bacteria** www.Life11e.com/ac25.1

Biologists estimate that the last common ancestor of the three domains lived about 3 billion years ago. We can deduce that it had DNA as its genetic material, and that its machinery for transcription and translation produced RNAs and proteins, respectively. This ancestor likely had a circular chromosome. All living organisms are the products of billions of years of mutation, natural selection, and genetic drift, and they are all well adapted to present-day environments. The earliest prokaryote fossils, which date back at least 3.5 billion years, indicate that there was considerable diversity among the prokaryotes even during those earliest days of life.

The small size of prokaryotes has hindered our study of their evolutionary relationships

Until about 300 years ago, nobody had even seen an individual prokaryote. Most prokaryotes remained invisible to humans until the invention of the first simple microscope. Prokaryotes are so small, however, that even the best light microscopes don't reveal much about them. It took advanced microscopic equipment and modern molecular techniques to open up the microbial world. (Microscopic organisms—both prokaryotes and eukaryotes—are often collectively referred to as “microbes.”)

Before DNA sequencing became practical, taxonomists based prokaryote classification on observable phenotypic characters such as shape, color, motility, nutritional requirements, and sensitivity to antibiotics. One of the characters most widely used to classify prokaryotes is the structure of their cell walls.

The cell walls of almost all bacteria contain [peptidoglycan](#), a cross-linked polymer of amino

sugars that produces a firm, protective, meshlike structure around the cell. Peptidoglycan is a substance unique to bacteria; its absence from the cell walls of archaea is a key difference between the two prokaryotic domains. Peptidoglycan is also an excellent target for combating pathogenic (disease-causing) bacteria because it has no counterpart in eukaryotic cells. Antibiotics such as penicillin and ampicillin, as well as other agents that specifically interfere with the synthesis of peptidoglycan-containing cell walls, tend to have little, if any, effect on the cells of humans and other eukaryotes.

peptidoglycan The cell wall material of many bacteria, consisting of a single enormous molecule that surrounds the entire cell.

The **Gram stain** is a technique that can be used to separate most types of bacteria into two distinct groups. A smear of bacterial cells on a microscope slide is soaked in a violet dye and treated with iodine; it is then washed with alcohol and counterstained with a red dye called safranin. **Gram-positive bacteria** retain the violet dye and appear blue to purple (**Figure 25.2A**). The alcohol washes the violet stain out of **Gram-negative bacteria**, which then pick up the safranin counterstain and appear pink to red (**Figure 25.2B**). For most bacteria, the effect of the Gram stain is determined by the chemical structure of the cell wall:

Gram stain A differential purple stain useful in characterizing bacteria. The peptidoglycan-rich cell walls of gram-positive bacteria stain purple; cell walls of gram-negative bacteria generally stain orange.

Gram-positive bacteria Bacteria that appear blue to purple when stained using the Gram-staining technique. These bacteria have an outer cell wall consisting of a thick layer of peptidoglycan.

Gram-negative bacteria Bacteria that appear red when stained using the Gram-staining technique. These bacteria have an outer membrane outside the relatively thin peptidoglycan layer of the cell wall.

A *Gram-negative cell wall* usually has a thin peptidoglycan layer, which is surrounded by a second, outer membrane quite distinct in chemical makeup from the cell membrane (see **Figure 25.2B**). Together the cell wall and the outer membrane are called the cell envelope. The space between the cell membrane and the outer membrane (known as the periplasmic space) contains proteins that are important in digesting some materials, transporting others, and detecting chemical gradients in the environment.

A *Gram-positive cell wall* usually has about five times as much peptidoglycan as a Gram-negative cell wall. Its thick peptidoglycan layer is a meshwork that may serve some of the same purposes as the periplasmic space of the Gram-negative cell envelope.

Shape is another phenotypic characteristic that is useful for the basic identification of bacteria. The three most common shapes are spheres, rods, and spiral forms (**Figure 25.3**). Many bacterial names are based on these shapes. A spherical bacterium is called a **coccus** (plural *cocci*). Cocci may live singly or may associate in two- or three-dimensional arrays such as chains, plates, blocks, or clusters of cells. A rod-shaped bacterium is called a **bacillus** (plural *bacilli*). A spiral bacterium (shaped like a corkscrew) is called a **spirillum** (plural *spirilla*). Bacilli and spirilla may be single, form chains, or gather in regular clusters. Among the other bacterial shapes are long filaments and branched filaments.

coccus (kock' us) (plural: cocci) [Gk. *kokkos*: berry, pit] Any of various spherical or spheroidal bacteria.

bacillus (bah sil' us) [L: little rod] Any of various rod-shaped bacteria.

spirillum Any of various spiral-shaped bacteria.

Figure 25.3 Bacterial Cell Shapes This composite, colorized micrograph shows the three most common bacterial shapes. Spherical cells are called cocci; those pictured are a species of *Enterococcus* from the mammalian gut. Rod-shaped cells are called bacilli; these *Escherichia coli* also reside in the gut. The helix-shaped spirilla are *Leptospira interrogans*, a human pathogen.

Less is known about the shapes of prokaryotic archaea because many of these organisms have never been seen. Many prokaryotic archaea are known only from samples of DNA from the environment. However, the species whose morphologies are known include cocci, bacilli, and even triangular and square species. Some flattened species grow on surfaces, arranged like sheets of postage stamps.

The nucleotide sequences of prokaryotes reveal their evolutionary relationships

Analyses of the nucleotide sequences of ribosomal RNA (rRNA) genes provided the first comprehensive evidence of evolutionary relationships among prokaryotes. Comparisons of rRNA genes are often used to identify microbes. For several reasons, rRNA is particularly useful for phylogenetic studies and identification purposes:

rRNA was present in the common ancestor of all life and is therefore evolutionarily ancient.

No free-living organism lacks rRNA, so rRNA genes can be compared across the tree of life.

rRNA plays a critical role in translation in all organisms, so lateral transfer of rRNA genes among distantly related species is unlikely.

rRNA has evolved slowly enough that gene sequences from even distantly related species can be aligned and analyzed.

Although studies of rRNA genes reveal much about the evolutionary relationships of

prokaryotes, they don't always reveal the entire evolutionary history of these organisms. In some groups of prokaryotes, analyses of multiple gene sequences have suggested several different phylogenetic patterns. How could such differences among different gene sequences arise? Studies of whole prokaryotic genomes have revealed that even distantly related prokaryotes sometimes exchange genetic material.

Lateral gene transfer can lead to discordant gene trees

As noted earlier, prokaryotes reproduce by binary fission. If we could follow these divisions back through evolutionary time, we would be tracing the complete tree of life. At a much broader scale, these divisions of organisms lead to splits among the major evolutionary lineages, or species of life (represented in highly abbreviated form in [Appendix A](#)). Because binary fission is an asexual process that replicates whole genomes, we would expect phylogenetic trees of prokaryotes constructed from most gene sequences (see [Chapter 22](#)) to reflect these same relationships.

Even though binary fission is an asexual process, there are other processes—including **[transformation, conjugation, and transduction](#)**—that allow the transfer of genetic information between some prokaryotes without reproduction. Thus prokaryotes can transfer and recombine their DNA with that of other individuals (this is sex in the genetic sense of the word), but this genetic exchange is not directly linked to reproduction, as it is in most eukaryotes.

From early in evolution to the present day, some genes have been moving “sideways” from one prokaryote species to another, a phenomenon known as **[lateral gene transfer](#)** (sometimes called horizontal gene transfer). Lateral gene transfers are well documented among closely related species, and some have been documented even across the domains of life.

lateral gene transfer The transfer of genes from one species to another, common among bacteria and archaea.
--

Consider, for example, the genome of *Thermotoga maritima*, a bacterium that can survive extremely high temperatures. By comparing the 1,869 gene sequences of *T. maritima* with sequences encoding the same proteins in other species, investigators found that some of this bacterium's genes have their closest relationships not with the genes of other bacterial species, but with the genes of archaea that live in similar extreme environments.

When genes involved in lateral transfer events are sequenced and analyzed, the resulting **[gene trees](#)** will not match the organismal tree in every respect (**Focus: Key Figure 25.4**). The individual gene trees will vary because the history of lateral transfer events is different for each gene. Biologists can reconstruct the underlying organismal phylogeny by comparing multiple genes (to produce a consensus tree) or by concentrating on genes that are unlikely to be involved in lateral gene transfer events. For example, genes that are involved in fundamental cellular processes (such as the rRNA genes discussed above) are unlikely to be replaced by the same genes from other species because functional, locally adapted copies of these genes are already present.

gene tree A graphic representation of the evolutionary relationships of a single gene in different species or of the members of a gene family.

What kinds of genes are most likely to be involved in lateral gene transfer? Genes that result in a new adaptation that confers higher fitness on a recipient species are most likely to be transferred repeatedly among species. For example, genes that produce antibiotic resistance are often transferred among bacterial species on plasmids, especially under the strong selection

pressure such as that imposed by modern antibiotic medications. Improper or overly frequent use of antibiotics can select for resistant strains of bacteria that are much harder to treat. This selection for antibiotic resistance explains why informed physicians have become more careful in prescribing antibiotics.

It is debatable whether lateral gene transfer has seriously complicated our attempts to resolve the tree of prokaryotic life. Recent work suggests that it has not. Lateral gene transfer rarely creates problems at higher taxonomic levels, even though it may complicate our understanding of the relationships among individual species. Some species clearly obtain some of their genes from otherwise distantly related species, so evolutionary histories of individual genes may differ within a single organism. But it is now possible to make nucleotide sequence comparisons involving entire genomes, and these studies are revealing a stable core of crucial genes that are uncomplicated by lateral gene transfer. Gene trees based on this stable core more accurately reveal the organismal phylogeny (see [Figure 25.4](#)). The problem remains, however, that only a very small proportion of the prokaryotic world has been described and studied.

focus: key figure

(B) Gene x tree

The apparent close relationship of C and D inferred from sequences of gene *x* reflects the lateral transfer of this gene rather than the phylogeny of the organisms.

(C) Consensus tree

A consensus tree based on multiple genes more accurately reflects the organismal phylogeny.

Figure 25.4 Lateral Gene Transfer Complicates Phylogenetic Relationships (A)

The phylogeny of four hypothetical prokaryote species, two of which have been involved in a lateral transfer of gene *x*. **(B)** A tree based only on gene *x* shows the phylogeny of the laterally transferred gene, rather than the organismal phylogeny. **(C)** A consensus tree based on multiple genes is more likely to reflect the true organismal phylogeny, especially if those genes come from a stable core of genes involved in fundamental processes.

Q: Why are multiple lateral gene transfers between the same two branches on a phylogeny expected to be rare, at least compared with similarities inherited through the stable core?

The great majority of prokaryote species have never been studied

Most prokaryotes have defied all attempts to grow them in pure culture, causing biologists to wonder how many species, and possibly even major clades, we might be missing. A window onto this problem was opened with the introduction of a new way of examining nucleic acid sequences. When biologists are unable to work with the whole genome of a single prokaryote species, they can instead examine genomes collected from an environmental sample (such as a scoop of sediment from the sea floor). This technique is known as [environmental genomics](#).

environmental genomics Sequencing technique used when biologists are unable to work with the whole genome of a prokaryote species but instead examine individual genes collected from a random sample of the organism's environment.

Biologists now routinely isolate gene sequences, or even whole genomes, from environmental samples such as soil and seawater. Comparing such sequences with previously known ones has revealed that an extraordinary number of the sequences represent new, previously unrecognized species. Biologists have described only about 10,000 species of bacteria and only a few hundred species of prokaryotic archaea (see [Figure 1.9](#)). The results of some environmental genomic studies suggest that there may be millions—perhaps hundreds of millions—of prokaryote species. Other biologists put the estimate much lower, arguing that the high dispersal ability of many bacterial species greatly reduces endemism (i.e., the number of species restricted to a small geographic area). Only the magnitude of these estimates differs, however; all sides agree that we have just begun to uncover Earth's prokaryotic diversity.

25.1 recap

Bacteria and Archaea are the two major divisions of the tree of life. Eukaryotes evolved from a group of prokaryotic archaea that captured and incorporated at least two different bacteria through endosymbiosis. Environmental genomic studies have revealed a much higher diversity of prokaryotes than was previously known.

learning outcomes

You should be able to:

- Compare and contrast the features of bacteria and prokaryotic archaea in a phylogenetic context.
- Distinguish between two scenarios for the contributions of bacteria and archaea to eukaryotes.
- Draw phylogenetic trees demonstrating the effects of lateral gene transfer.

1. What findings led to the establishment of Bacteria and Archaea as separate domains?
2. The figure at right shows an organismal tree in which gene **x** has undergone a lateral transfer event. Draw the phylogenetic tree you would expect based on gene **x**, as well as the phylogenetic tree you would expect based on a consensus of non-transferred genes.

3. How did eukaryotes arise through evolutionary contributions from both prokaryotic archaea and bacteria?

Despite the challenges of reconstructing prokaryote phylogeny, taxonomists are starting to establish evolutionary classification systems for these organisms. With a full understanding that new information requires periodic revisions in these classifications, we will next apply a current system of classification to organize our survey of prokaryote diversity.

***connect the concepts** The origin of mitochondria and chloroplasts by endosymbiosis is described in [Key Concepts 5.5](#) and [27.1](#).

***connect the concepts** Prokaryote exchange of genetic material by conjugation and transformation is described in [Key Concepts 12.6](#) and [13.1](#), respectively.

25.2 Prokaryote Diversity Reflects the Ancient Origins of Life

The prokaryotes were alone on Earth for a very long time, adapting to new environments and to changes in existing environments. They have survived to this day, in massive numbers and incredible diversity, and they are found everywhere. In numbers of individuals, prokaryotes are far more abundant than eukaryotes. Individual prokaryotes in the oceans number more than 3×10^{28} —more than the number of stars in the universe. Closer to home, the individual bacteria living in your intestinal tract outnumber all the humans who have ever lived.

focus your learning

Prokaryotes are classified based on the sequences of their genomes.

Given our still-fragmentary knowledge of prokaryote diversity, it is not surprising that there are many different hypotheses about the relationships of the major groups of prokaryotes. In this book we use a classification system that has considerable support from nucleotide sequence data. We will discuss eight major bacterial groups that have the broadest phylogenetic support and have received the most study: hadobacteria, hyperthermophilic bacteria, firmicutes, actinobacteria, cyanobacteria, spirochetes, chlamydias, and proteobacteria (see [Figure 25.1](#)). Many other major groups of bacteria are known but are less thoroughly studied. We will then describe the prokaryotic archaea, whose diversity is even less well studied than that of the bacteria.

Two early-branching lineages of bacteria live at very high temperatures

Several lineages of bacteria and archaea are **extremophiles**: they thrive under extreme conditions that would kill most other organisms. The **hadobacteria**, for example, are thermophiles (Greek, “heat lovers”). The group’s name is derived from Hades, the ancient Greek name for the underworld. Hadobacteria of the genus *Deinococcus* are resistant to radiation and can degrade nuclear waste and other toxic materials. They can also survive extremes of cold as well as hot temperatures. Another hadobacterium, *Thermus aquaticus*, was the source of the thermally stable DNA polymerase that was critical for the development of the polymerase chain reaction. *Thermus aquaticus* was originally isolated from a hot spring, but it can be found wherever hot water occurs (including in many residential hot-water heaters).

extremophiles Archaea and bacteria that live and thrive under conditions (e.g., extremely high temperatures) that would kill most organisms.

The **hyperthermophilic bacteria** are another major group of extremophiles. Genera such as *Aquifex* live near volcanic vents and in hot springs, sometimes at temperatures near the boiling point of water. Some species of *Aquifex* need only hydrogen, oxygen, carbon dioxide, and mineral salts to live and grow. Species of the genus *Thermotoga* live deep underground in oil reservoirs as well as in other high-temperature environments.

Biologists have hypothesized that high temperatures characterized the ancestral conditions for life, given that most environments on early Earth were much hotter than those of today.

Reconstructions of ancestral bacterial genes have supported this hypothesis by showing that the ancestral sequences functioned best at elevated temperatures. The presence of multiple lineages of extremophiles at the base of the bacterial tree (see [Figure 25.1](#)) also provides support for the origin of life in a high-temperature environment.

Firmicutes include some of the smallest cellular organisms

The **firmicutes** are also known as low-GC Gram-positive bacteria. The first part of this description (low-GC) derives from the relatively low ratio of G-C to A-T nucleotide base pairs in their DNA. The second part (Gram-positive) is less accurate: some of the firmicutes are in fact Gram-negative, and some have no cell wall at all. Despite these differences, phylogenetic analyses of DNA sequences support the monophyly of this bacterial group.

One group of firmicutes can produce resting structures called [endospores](#) ([Figure 25.5](#)). When a key nutrient such as nitrogen or carbon becomes scarce, the bacterium replicates its DNA and encapsulates one copy, along with some of its cytoplasm, in a tough endospore wall heavily thickened with peptidoglycan and surrounded by a spore coat. The parent cell then breaks down, releasing the endospore. Endospore production is not a reproductive process, as the endospore merely replaces the parent cell. The endospore, however, can survive harsh environmental conditions that would kill the parent cell, such as high or low temperatures or drought, because it is dormant—its normal metabolic activity is suspended. Later, if it encounters favorable conditions, the endospore becomes metabolically active and divides, forming new cells that are like the parent cell. Members of this endospore-forming group include the many species of *Clostridium* and *Bacillus*. Some of their endospores can be reactivated after more than 1,000 years of dormancy. There are even credible claims of reactivation of *Bacillus* endospores that are millions of years old.

endospore [Gk. *endo*: within + *spora*: to sow] In some bacteria, a resting structure that can survive harsh environmental conditions.

Figure 25.5 A Structure for Waiting Out Bad Times Under harsh conditions, some firmicutes can replicate their DNA and encase it in an endospore. The parent cell then breaks down, and the endospore survives in a dormant state until conditions improve.

Endospores of *Bacillus anthracis* are the cause of anthrax. Anthrax is primarily a disease of cattle and sheep, but it can be fatal in humans. When the endospores sense macrophages in mammalian blood, they reactivate and release toxins into the bloodstream. *Bacillus anthracis* has been used as a bioterrorism agent because it is relatively easy to transport large quantities of its endospores and release them among human populations, where they may be inhaled or ingested.

Members of the genus *Staphylococcus*—the **staphylococci** ([Figure 25.6](#))—are abundant on the human body surface; they are responsible for boils and many other skin problems. *Staphylococcus aureus* is the best-known human pathogen in this genus; it is present in 20 to 40 percent of normal adults (and in 50–70% of hospitalized adults). In addition to skin diseases, *S. aureus* can cause respiratory, intestinal, and wound infections.

Figure 25.6 Staphylococci “Grape clusters” are the usual arrangement of these firmicutes, which are often the cause of skin or wound infections.

Another interesting group of firmicutes, the **mycoplasmas**, lack cell walls, although some have a stiffening material outside the cell membrane. The mycoplasmas are among the smallest cellular organisms known ([Figure 25.7](#)). The smallest mycoplasmas have a diameter of about 0.2 μm. They are small in another crucial sense as well: they have less than half as much DNA as most other prokaryotes. It has been speculated that the DNA in a mycoplasma, which codes for fewer than 500 proteins, may be close to the minimum amount required to encode the essential properties of a living cell.

Figure 25.7 Tiny Cells With about one-fifth as much DNA as *E. coli*, mycoplasmas are among the smallest known bacteria.

Actinobacteria include major pathogens as well as valuable sources of antibiotics

Actinobacteria, also known as high-GC Gram-positive bacteria, have a higher ratio of G-C to A-T nucleotide base pairs than do the firmicutes (low-GC Gram-positives). These bacteria develop an elaborately branched system of filaments (**Figure 25.8**) that resembles the filamentous growth habit of fungi, albeit at a smaller scale. Some actinobacteria reproduce by forming chains of spores at the tips of the filaments. In species that do not form spores, the branched, filamentous growth ceases and the structure breaks up into typical cocci or bacilli, which then reproduce by binary fission.

actin [Gk. *aktis*: ray] A protein that makes up the cytoskeletal microfilaments in eukaryotic cells and is one of the two contractile proteins in muscle. (See *also* myosin.)

Figure 25.8 Actinobacteria Often Produce Branching Filaments The tangled, branching filaments seen in this scanning electron micrograph are typical of this medically important bacterial group.

The actinobacteria include several medically important bacteria. *Mycobacterium tuberculosis* causes tuberculosis, which kills 3 million people each year. Genetic data suggest that this bacterium may have been infecting our ancestors for almost 3 million years, making it the oldest known human bacterial pathogen. The genus *Streptomyces* produces streptomycin as well as hundreds of other antibiotics. We derive most of our antibiotics from actinobacteria.

Cyanobacteria were the first photosynthesizers

Cyanobacteria, sometimes called blue-green bacteria because of their pigmentation, are photosynthetic. They use chlorophyll *a* for photosynthesis and release oxygen gas (O₂); many species also fix nitrogen (which we will discuss in [Key Concept 25.3](#)). The production of oxygen by these bacteria transformed the atmosphere of early Earth (see [Key Concept 24.2](#)).

Cyanobacteria carry out the same type of photosynthesis that is characteristic of eukaryotic photosynthesizers. They contain elaborate and highly organized internal membrane systems called [photosynthetic lamellae](#). As mentioned in [Key Concept 25.1](#), the chloroplasts of photosynthetic eukaryotes are derived from an endosymbiotic cyanobacterium.

photosynthetic lamellae The internal membrane system of the cyanobacteria.

Cyanobacteria may live free as single cells or associate in multicellular colonies. Depending on the species and on growth conditions, these colonies may range from flat sheets one cell thick to filaments to spherical balls of cells. Some filamentous colonies of cyanobacteria differentiate into three specialized cell types: vegetative cells, spores, and heterocysts ([Figure 25.9](#)). [Vegetative cells](#) photosynthesize, [spores](#) are resting stages that can survive harsh environmental conditions and eventually develop into new filaments, and [heterocysts](#) are cells specialized for nitrogen fixation. All of the known cyanobacteria with heterocysts fix nitrogen. Heterocysts also have a role in reproduction: when filaments break apart to reproduce, the

heterocyst may serve as a breaking point.

(A) *Anabaena* sp.

(B) *Nostoc punctiforme*

A thick wall separates the cytoplasm of the nitrogen-fixing heterocyst from the surrounding environment.

(C)

Figure 25.9 Cyanobacteria (A) Some cyanobacteria form filamentous colonies containing three cell types. (B) Heterocysts are specialized for nitrogen fixation and may serve as a breaking point when filaments reproduce. (C) This pond in Canada has experienced eutrophication: phosphorus and other nutrients generated by human activity have accumulated, feeding an immense green mat (commonly referred to as “pond scum”) that is made up of several species of free-living cyanobacteria.

Media Clip 25.1 **Cyanobacteria** www.Life11e.com/mc25.1

vegetative Nonreproductive, nonflowering, or asexual.

spore [Gk. *spora*: seed] (1) Any asexual reproductive cell capable of developing into an adult organism without gametic fusion. In plants, haploid spores develop into gametophytes, diploid spores into sporophytes. (2) In prokaryotes, a resistant cell capable of surviving unfavorable periods.

heterocyst A large, thick-walled cell type in the filaments of certain cyanobacteria that performs nitrogen fixation.

Spirochetes move by means of axial filaments

Spirochetes are Gram-negative, motile bacteria characterized by a unique structure known as an axial filament, which is composed of multiple internal flagella running through the periplasmic space (**Figure 25.10A**). The cell body is a long cylinder coiled into a helix (**Figure 25.10B**). The internal flagellae begin at either end of the cell and overlap in the middle. Motor proteins connect the axial filament to the cell wall, enabling the corkscrew-like movement of the bacterium. Many spirochetes are parasites of humans; a few are pathogens, including those that cause syphilis

and Lyme disease. Others live free in mud or water.

Figure 25.10 Spirochetes Get Their Shape from Axial Filaments (A) A spirochete from the gut of a termite, seen in cross section, shows the internal flagellae that compose the axial filament, which these helical prokaryotes use to produce a corkscrew-like movement. **(B)** This spirochete species causes syphilis in humans.

Chlamydias are extremely small parasites

Chlamydias are among the smaller bacteria (0.2–1.5 μ m in diameter). They can live only as parasites in the cells of other organisms. It was once believed that their obligate parasitism resulted from an inability to produce ATP—that chlamydias were “energy parasites.” However, genome sequencing indicates that chlamydias have the genetic capacity to produce at least some ATP. They can augment this capacity by using an enzyme called a translocase, which allows them to take up ATP from the cytoplasm of their host in exchange for ADP from their own

cells.

These tiny, Gram-negative cocci are unique among prokaryotes because of a complex life cycle that involves two different forms of cells, elementary bodies and reticulate bodies ([Figure 25.11](#)). Various strains of chlamydias cause eye infections (especially trachoma), sexually transmitted diseases, and some forms of pneumonia in humans.

Figure 25.11 Chlamydias Change Form Elementary bodies and reticulate bodies are the two cell forms of the chlamydia life cycle.

The proteobacteria are a large and diverse group

By far the largest bacterial group, in terms of numbers of described species, is the **proteobacteria**. The proteobacteria include many species of Gram-negative photoautotrophs (see [Key Concept 25.3](#)) that use light-driven reactions to metabolize sulfur, as well as dramatically diverse bacteria that bear no phenotypic resemblance to the photoautotrophic species. Genetic and morphological evidence indicates that the mitochondria of eukaryotes were derived from a proteobacterium by endosymbiosis.

Among the proteobacteria are some nitrogen-fixing genera, such as *Rhizobium*, and other bacteria that contribute to the global nitrogen and sulfur cycles. *Escherichia coli*, one of the most studied organisms on Earth, is a proteobacterium. So, too, are many of the most famous human pathogens, such as *Yersinia pestis* (which causes bubonic plague), *Vibrio cholerae* (cholera), and *Salmonella typhimurium* (gastrointestinal disease; [Figure 25.12](#)).

Figure 25.12 Proteobacteria Include Many Familiar Bacteria These conjugating cells of *Salmonella typhimurium* are exchanging genetic material. This pathogen causes a wide range of gastrointestinal illnesses in humans.

Media Clip 25.2 A Swarm of *Salmonella* www.Life11e.com/mc25.2

The bioluminescent *Vibrio* we discussed at the opening of this chapter are also members of this group. There are many potential applications of the genes that encode bioluminescent proteins in bacteria. Already, these genes are being inserted into the genomes of other species in which the resulting bioluminescence is used as a marker of gene expression. Futuristic proposals for making use of bioluminescence in bioengineered organisms include crop plants that glow when they become water-stressed and need to be irrigated, and glowing trees that could light highways at night in place of electric lights.

Although fungi cause most plant diseases, and viruses cause others, about 200 known plant diseases are of bacterial origin. Crown gall, with its characteristic tumors ([Figure 25.13](#)), is one of the most striking. The causal agent of crown gall is *Agrobacterium tumefaciens*, a proteobacterium that harbors a plasmid used in recombinant DNA studies as a vehicle for inserting genes into new plant hosts.

Euonymus sp.

Figure 25.13 Crown Gall Crown gall, a type of tumor shown here growing on the stem of a *Euonymus* shrub, is caused by the proteobacterium *Agrobacterium tumefaciens*.

Gene sequencing enabled biologists to differentiate Archaea from Bacteria

The original identification of Archaea as a group distinct from Bacteria was based on phylogenetic relationships determined from rRNA gene sequences. This separation was supported when biologists sequenced the first complete archaeal genome, which consisted of 1,738 genes — more than half of which were unlike any genes ever found in Bacteria.

Prokaryotic archaea are known for living in extreme habitats such as those with high salinity (salt content), low oxygen concentrations, high temperatures, or high or low pH ([Figure 25.14](#)). Many prokaryotic archaea are not extremophiles, however—they are common in soil, for example. Perhaps the largest numbers of prokaryotic archaea live in the ocean depths. None are known to be pathogens of any eukaryotes.

experiment

Figure 25.14A What Is the Highest Temperature Compatible with Life?

Original Paper: Kashefi, K. and D. R. Lovley. 2003. Extending the upper temperature limit for life. *Science* 301: 934.

Can any organism thrive at temperatures above 120°C? This is the temperature used for sterilization, known to destroy all previously described organisms. Kazem Kashefi and Derek Lovley isolated an unidentified prokaryote from water samples taken near a hydrothermal vent and found it survived and even multiplied at 121°C. The organism was dubbed "Strain 121," and its gene sequencing results indicate that it is a prokaryotic archaeal species.

HYPOTHESIS▶ Some prokaryotes can survive at temperatures above 120°C.

METHOD

1. Seal samples of unidentified, iron-reducing, thermal vent prokaryotes in tubes with a medium containing Fe^{3+} as an electron acceptor. Control tubes contain Fe^{3+} but no organisms.
2. Hold both tubes in a sterilizer at 121°C for 10 hours. If the iron-reducing organisms are metabolically active, they will reduce the Fe^{3+} to Fe^{2+} (as magnetite, which can be detected with a magnet).

RESULTS

The solids are attracted to the magnet, indicating that the organisms in this solution are alive and engaged in iron-reducing biochemical reactions.

Heating to 121°C sterilizes the control solution.

CONCLUSION▶ Prokaryotic archaea of "Strain 121" can survive at temperatures above the previously defined sterilization limit.

work with the data

Figure 25.14B What is the Highest Temperature Compatible with Life?

Original Paper: Kashefi, K. and D. R. Lovley. 2003.

After Kashefi and Lovley isolated Strain 121, they examined its growth at various temperatures. The table below shows generation time (time between cell divisions) at nine temperatures.

Temperature °C	Generation time (hr)
85	10
90	4
95	3
100	2.5
105	2
110	4
115	6
120	20
130	No growth, but cells not killed

QUESTIONS

1. Make a graph from these data showing time as a function of temperature.
2. Which temperature appears to be closest to the optimum for the growth of Strain 121?
3. Note that no growth occurred at 130°C, but that the cells were not killed. How would you demonstrate that these cells were still alive?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

There are five major groups of prokaryotic archaea (see [Figure 25.1](#)): **Euryarchaeota**, **Crenarchaeota**, **Thaumarchaeota**, **Korarchaeota**, and **Lokiarchaeota**. The Lokiarchaeota are of particular interest because recent studies of their genomes show that they are the closest known living relatives of eukaryotes.

Two characteristics shared by all prokaryotic archaea are the absence of peptidoglycan in their cell walls and the presence of lipids of distinctive composition in their cell membranes (see [Table 25.1](#)). The unusual lipids in the membranes of prokaryotic archaea are found in no bacteria or eukaryotes. Most lipids in bacterial and eukaryotic membranes contain unbranched long-chain fatty acids connected to glycerol molecules by **ester linkages**:

In contrast, some lipids in membranes of prokaryotic archaea contain long-chain hydrocarbons connected to glycerol molecules by **ether linkages**:

ether linkage The linkage of two hydrocarbons by an oxygen atom ($\text{HC}-\text{O}-\text{CH}$). Ether linkages are characteristic of the membrane lipids of the Archaea. (Contrast with ester linkage.)

ester linkage A condensation (water-releasing) reaction in which the carboxyl group of a fatty acid reacts with the hydroxyl group of an alcohol. Lipids, including most membrane lipids, are formed in this way. (Contrast with ether linkage.)

In addition, the long hydrocarbon chains in the lipids of prokaryotic archaea are branched. One class of archaeal lipids contains glycerol at *both* ends of the hydrocarbons ([Figure 25.15](#)). These lipids form a lipid monolayer structure that is unique to prokaryotic archaea. They still fit into a biological membrane because they are twice as long as the typical lipids in the bilayers of other membranes. Lipid monolayers and bilayers are both found among the prokaryotic archaea. The effects, if any, of these structural features on membrane performance are unknown.

Figure 25.15 Membrane Architecture in Prokaryotic Archaea The long-chain hydrocarbons of many prokaryotic archaeal lipids have glycerol molecules at both ends, so that the membranes they form consist of a lipid monolayer. In contrast, the membranes of other archaea, bacteria, and eukaryotes consist of a lipid bilayer.

Prokaryotic archaea live in extremely diverse environments

Most known crenarchaeotes are either thermophilic, acidophilic (acid loving), or both. Members of the genus *Sulfolobus* live in hot sulfur springs at temperatures of 70°C to 75°C. They become metabolically inactive at 55°C (131°F). Hot sulfur springs are also extremely acidic. *Sulfolobus* grows best in the range from pH 2 to pH 3, but some members of this genus readily tolerate pH values as low as 0.9. Most acidophilic thermophiles maintain an internal pH of 5.5 to 7 (close to neutral) in spite of their acidic environment. These and other crenarchaeotes thrive where very

few other organisms can even survive ([Figure 25.16](#)).

Figure 25.16 Some Crenarchaeotes Like It Hot Thermophilic crenarchaeotes can thrive in the intense heat of volcanic hot sulfur springs such as these in Yellowstone National Park.

Some species of euryarchaeotes are [methanogens](#): they produce methane (CH_4) by reducing carbon dioxide as the key step in their energy metabolism. All of the methanogens are obligate anaerobes (see [Key Concept 25.3](#)). Comparison of their rRNA gene sequences has revealed a close evolutionary relationship among these methanogenic species, which were previously assigned to several different groups of bacteria.

methanogens Methane-producing microbes.
--

Methanogenic euryarchaeotes release approximately 2 billion tons of methane gas into Earth's atmosphere each year, accounting for 80 to 90 percent of the methane that enters the atmosphere, including that produced in some mammalian digestive systems. Approximately a third of this methane comes from methanogens living in the guts of ruminants such as cattle, sheep, and deer, and another large fraction comes from methanogens living in the guts of termites and cockroaches. Methane is increasing in Earth's atmosphere by about 1 percent per year and contributes to the greenhouse effect. Part of that increase is due to increases in cattle and rice production and the methanogens associated with both.

Another group of euryarchaeotes, the [extreme halophiles](#) (salt lovers), live exclusively in very salty environments. Because they contain pink carotenoid pigments, these archaea are sometimes easy to see ([Figure 25.17](#)). Extreme halophiles grow in the Dead Sea and in brines of all types. The reddish pink spots that can occur on pickled fish are colonies of halophilic archaea. Few other organisms can live in the saltiest homes that the extreme halophiles occupy — most would “dry” to death, losing too much water to the hypertonic environment. Extreme halophiles have been found in lakes with pH values as high as 11.5. These are the most alkaline environments inhabited by living organisms, and almost as alkaline as household ammonia.

extreme halophiles A group of euryarchaeotes that live exclusively in very salty environments.

Figure 25.17 Extreme Halophiles Highly saline environments such as these commercial seawater evaporating ponds in San Francisco Bay are home to extreme halophiles. The prokaryotic archaea are easily visible here because of the rich red coloration of their carotenoid pigments

Some of the extreme halophiles have a unique system for trapping light energy and using it to form ATP—without using any form of chlorophyll—when oxygen is in short supply. They use the pigment retinal (also found in the vertebrate eye) combined with a protein to form a light-absorbing molecule called microbial rhodopsin.

Another member of the Euryarchaeota, *Thermoplasma*, has no cell wall. It is thermophilic and acidophilic, its metabolism is aerobic, and it lives in coal deposits. Its genome of 1,100,000 base pairs is among the smallest (along with that of the mycoplasmas) found in any free-living organism, although some parasitic organisms have even smaller genomes.

Most known prokaryotic archaea are crenarchaeotes or euryarchaeotes, but studies of extreme environments have identified several small lineages that are not closely related to either of these major groups. For example, the korarchaeotes and thaumarchaeotes are known only from DNA isolated directly from hot environments. Neither group has been grown successfully in pure culture. The thaumarchaeotes oxidize ammonia and may play an important role in the nitrogen cycle.

The lokiarchaeotes were discovered in 2015 by sequencing environmental samples from near a hydrothermal vent called Loki's Castle deep in the Arctic Ocean. An organism's genome was detected and sequenced from this deep-sea sample, although the organism has not yet been cultured. Sequence analysis revealed that the organism was a distinct lineage of archaea, which was named *Lokiarchaeum*. Of particular interest was the finding that the *Lokiarchaeum* genome contains a large number of genes with cell membrane-related functions—genes and functions

that had previously been known to occur only in eukaryotes. Phylogenetic analysis of eukaryote, *Lokiarchaeum*, and other archaeal genomes shows that *Lokiarchaeum* is more closely related to eukaryotes than it is to any other prokaryotes (see [Figure 25.1](#)). Some of the genes found in *Lokiarchaeum* are similar to genes that function in eukaryotes in controlling cell shape and cytoskeleton formation. These findings suggest that *Lokiarchaeum* is the closest known prokaryotic relative of eukaryotes, and this fascinating organism may share some characteristics that have previously been thought to be found only in eukaryotes.

25.2 recap

Bacteria and Archaea are highly diverse groups that survive in almost every imaginable habitat on Earth. Many prokaryotes can survive and even thrive in habitats where no eukaryotes can live, including extremely hot, acidic, or saline conditions. Eukaryotes are most closely related to some lineages of prokaryotic archaea, although endosymbioses of bacteria within eukaryotic cells contributed to the evolution of eukaryotic organelles.

learning outcomes

You should be able to:

- Interpret a phylogenetic tree of major lineages of Bacteria and Archaea and use it to explain (a) the difference between a prokaryote and a eukaryote, and (b) how prokaryotic archaea and bacteria both contributed to the evolution of eukaryotes.
-
1. Consider the difference between prokaryotes and eukaryotes shown in [Table 25.1](#). Why might eukaryotes be more like prokaryotic archaea in some features and more like bacteria in others?
 2. Given that all species of life have evolved for the same amount of time since their common origin, how would you respond to someone who characterizes prokaryotes as “primitive”? Include at least two examples of major groups of prokaryotes to support your answer.

Prokaryotes are found almost everywhere on Earth and live in a wide variety of ecosystems. In the next section we will examine the contributions of prokaryotes to the functioning of those ecosystems.

25.3 Ecological Communities Depend on Prokaryotes

Prokaryotic cells do not usually live in isolation. Rather, they live in communities of many different species, often including microscopic eukaryotes. Whereas some microbial communities are harmful to humans, others provide important services. They help us digest our food, break down municipal waste, and recycle organic matter and chemical elements in the environment.

focus your learning

Microbiomes are critical to the health of many eukaryotes.

Prokaryotes differ with respect to oxygen metabolism.

Prokaryotes play important roles in nitrogen cycling.

Many prokaryotes form complex communities

Some microbial communities form layers in sediments, and others form clumps a meter or more in diameter. Many microbial communities tend to form dense **biofilms**. Upon contacting a solid surface, the cells bind to that surface and secrete a sticky, gel-like polysaccharide matrix that traps other cells (**Figure 25.18**). Once a biofilm forms, the cells become more difficult to kill.

biofilm A community of microorganisms embedded in a polysaccharide matrix, forming a highly resistant coating on almost any moist surface.

(A) Recruitment of organisms for biofilm community

(B) Dental plaque: A living biofilm community

Figure 25.18 Forming a Biofilm (A) Free-living prokaryotes readily attach themselves to surfaces and form films that are stabilized and protected by a surrounding matrix. Once the population is large enough, the developing biofilm can send out chemical signals that attract other microorganisms. **(B)** Scanning electron micrography reveals a biofilm of dental plaque. The bacteria (red) are embedded in a matrix consisting of proteins from both bacterial secretions and saliva.

Biofilms are found in many places, and in some of those places they cause problems for humans. The material on our teeth that we call dental plaque is a biofilm. Pathogenic bacteria are difficult for the immune system—and modern medicine—to combat once they form a biofilm, which may be impermeable to antibiotics. Worse, some drugs stimulate the bacteria in a biofilm to lay down more matrix, making the film even more impermeable. Biofilms may form on just about any available surface, including contact lenses and artificial joint replacements. They foul metal pipes and cause corrosion, a major problem in steam-driven electricity generation plants. Fossil stromatolites—large, rocky structures made up of alternating layers of fossilized biofilm and calcium carbonate—are among the oldest remnants of life on Earth (see [Figure 24.9B](#)).

Some biologists are studying the chemical signals that prokaryotes use to communicate with one another and that trigger density-linked activities such as biofilm formation. We saw one example of this type of communication—called [quorum sensing](#)—in the chapter-opening discussion of bioluminescent *Vibrio*. How does quorum sensing work? As demonstrated in **Investigating Life: How Do Bacteria Communicate with One Another?**, individual *Vibrio*

bacteria can excrete a signal that is detected by other individuals, and this signal then functions to turn on the genes that produce luciferase—an enzyme that produces bioluminescence when it is active.

quorum sensing The use of chemical communication signals to trigger density-linked activities such as biofilm formation in prokaryotes.

Microbiomes are critical to the health of many eukaryotes

Although only a few bacterial species are pathogens, popular notions of bacteria as “germs” and fear of the consequences of infection cause many people to assume that most bacteria are harmful. Increasingly, however, biologists are discovering that the health of humans (as well as that of most other eukaryotes) depends in large part on the health of our microbiomes: the communities of bacteria and prokaryotic archaea that live in and on our bodies. Other communities of microbes live in close association with other multicellular organisms.

Every surface of your body is covered with diverse communities of bacteria ([Figure 25.19](#)). A recent study identified more than 1,000 species of bacteria that live on human skin. Inside your body, your digestive system teems with bacteria. When these communities are disrupted, they must be restored before the body can function normally.

Figure 25.19 The Body's Microbiome Is Critical to the Maintenance of Health

Surveys of the human microbiome have shown that this community includes thousands of diverse bacterial species that are adapted to grow in or on various parts of the body. Although we now know that the composition of this microbiome is closely associated with many aspects of human health, most of the component species are poorly characterized and remain largely unstudied by biologists. What has become clear is that, although the “subcommunities” in different parts of the body share similarities, each is a site-specific assemblage of many distinctive species.

investigatinglife How Do Bacteria Communicate with One Another? experiment

experiment

Original Paper: Miller, M. B. and B. L. Bassler. 2001. Quorum sensing in bacteria. *Annual Review of Microbiology* 55:165–199.

Bonnie Bassler and her colleagues at Princeton University investigated how *Vibrio fischeri* bacteria communicate with one another. These bacteria produce bioluminescence when they are present in sufficiently high densities. In a normal *V. fischeri* bacterium, the following pathway produces bioluminescence when a bacterial colony becomes dense enough to produce sufficient signal:

The fact that the bacteria emit light only when they are present in high densities suggests that the signal is used to communicate among nearby bacteria, alerting one another to their presence. But how can we tell that the signal produced by one bacterium is being received by another?

HYPOTHESIS *V. fischeri* can transmit the signal molecule from one individual to another, thus communicating about the presence of other nearby bacteria.

METHOD

1. Select two mutant strains of *V. fischeri* incapable of emitting light on their own. In strain A, a mutation for the signal receptor renders the bacteria unable to detect the signal molecule, so they do not bioluminesce:

Strain B bacteria have a mutated signal gene, so they do not produce a signal molecule, although the receptor and the luciferase gene are normal:

2. Incubate samples of *V. fischeri* on agar petri plates, as follows:

Plate 1: Strain A only
 Plate 2: Strain B only
 Plate 3: Half of plate with Strain A, half with Strain B

RESULTS

CONCLUSION *Vibrio* bacteria can detect the signal molecule produced by other nearby bacteria and use this information to detect the presence of other bacteria.

Biologists are discovering that many complex health problems are linked to the disruption of our microbiomes. These diverse microbial communities affect the expression of our genes and play a critical role in the development and maintenance of a healthy immune system. When our microbiomes contain an appropriate community of beneficial species, our bodies function normally. But these communities are strongly affected by our life experiences, by the food we eat, by the medicines we take, and by our exposure to various environmental toxins. The recent

rapid increase in the rate of autoimmune diseases in humans—diseases in which the immune system begins to attack the body—has been linked to the changing diversity and composition of our microbiomes.

The early acquisition of an appropriate microbiome is critical for lifelong health. Normally, a human infant acquires much of its microbiome at birth, from the microbiome in its mother's vagina. Other components of the microbiome are also acquired from the mother, especially through breast feeding. Recent studies have shown that babies born by cesarean section, as well as babies that are bottlefed on artificial milk formula, typically acquire microbes from a wider variety of sources. Many of the bacteria acquired in this way are not well suited for human health. Biologists have discovered that the incidence of many autoimmune diseases is much higher in people who were born by cesarean section and in those who were fed on formula as infants, compared with individuals who were born vaginally and breast-fed as infants. The difference appears to be related to the composition of the individual's original microbiome.

Humans use some of the metabolic products—especially vitamins B₁₂ and K—produced by the microbiome living in the large intestine. Communities of bacteria line our intestines with a dense biofilm that is in intimate contact with the mucosal lining of the gut. This biofilm facilitates nutrient transfer from the intestine into the body, functioning like a specialized “tissue” that is essential to our health. This biofilm has a complex ecology that scientists have just begun to explore in detail—including the possibility that the species composition of an individual's gut microbiome may contribute to obesity.

Animals harbor a variety of microbes in their digestive tracts, many of which play important roles in digestion. Cattle depend on prokaryotes to break down plant material. Like most animals, cattle cannot produce cellulase, the enzyme needed to start the digestion of the cellulose that makes up the bulk of their plant food. However, bacteria living in a special section of the gut, called the rumen, produce enough cellulase to process the daily diet for the cattle.

A small minority of bacteria are pathogens

The late nineteenth century was a productive era in the history of medicine—a time when bacteriologists, chemists, and physicians proved that many diseases are caused by microbial agents. During this time, the German physician Robert Koch laid down a set of four rules for establishing that a particular microorganism causes a particular disease:

- . The microorganism is always found in individuals with the disease.
- . The microorganism can be taken from the host and grown in pure culture.
- . A sample of the culture produces the same disease when injected into a new, healthy host.
- . The newly infected host yields a new, pure culture of microorganisms identical to those obtained in the second step.

These rules, called Koch's postulates, were important tools in a time when it was not widely understood that microorganisms cause disease. Although modern medical science has more powerful diagnostic tools, Koch's postulates remain useful. For example, physicians were taken aback in the 1980s when stomach ulcers—long accepted and treated as the result of excess stomach acid—were shown by Koch's postulates to be caused by the bacterium *Helicobacter pylori* ([Figure 25.20](#)).

Figure 25.20 Satisfying Koch's Postulates Robin Warren and Barry Marshall of the University of Western Australia won the 2005 Nobel Prize in Medicine for showing that ulcers are caused not by the action of stomach acid but by infection with the bacterium *Helicobacter pylori*.

For an organism to be a successful pathogen, it must:

arrive at the body surface of a potential host;

enter the host's body;

evade the host's defenses;

reproduce inside the host; and

infect a new host.

Failure to complete any of these steps ends the disease cycle of a pathogenic organism. Yet in spite of the many defenses available to potential hosts, some bacteria are very successful pathogens. Pathogenic bacteria are often surprisingly difficult to combat, even with today's arsenal of antibiotics. One source of this difficulty is their ability to form biofilms.

For the host, the consequences of a bacterial infection depend on several factors. One is the invasiveness of the pathogen: its ability to multiply in the host's body. Another is its toxigenicity: its ability to produce toxins (chemical substances that are harmful to the host's tissues).

Corynebacterium diphtheriae, the agent that causes diphtheria, has low invasiveness and multiplies only in the throat, but its toxigenicity is so great that the entire body is affected. In contrast, *Bacillus anthracis*, which causes anthrax, has low toxigenicity but is so invasive that the entire bloodstream ultimately teems with the bacteria.

There are two general types of bacterial toxins: exotoxins and endotoxins. Endotoxins are released when certain bacteria grow or lyse (burst). **Endotoxins** are lipopolysaccharides (complexes consisting of a polysaccharide and a lipid component) that form part of the outer bacterial membrane. Endotoxins are rarely fatal to the host; they normally cause fever, vomiting, and diarrhea. Among the endotoxin producers are some strains of the proteobacteria *Salmonella* and *Escherichia*.

endotoxin A lipopolysaccharide that forms part of the outer membrane of certain Gram-

negative bacteria that is released when the bacteria grow or lyse. (Contrast with exotoxin.)

Exotoxins are soluble proteins released by living, multiplying bacteria. They are highly toxic—often fatal—to the host. Human diseases induced by bacterial exotoxins include tetanus (*Clostridium tetani*), cholera (*Vibrio cholerae*), and bubonic plague (*Yersinia pestis*). Anthrax is caused by three exotoxins produced by *Bacillus anthracis*. Botulism is caused by exotoxins produced by *Clostridium botulinum*; these exotoxins are among the most poisonous ever discovered. The lethal dose for humans of one exotoxin of *C. botulinum* is about one-millionth of a gram. Nonetheless, much smaller doses of this exotoxin, marketed under various trade names (e.g., Botox), are used to treat muscle spasms and for cosmetic purposes (temporary wrinkle reduction in the skin).

exotoxin A highly toxic, usually soluble protein released by living, multiplying bacteria. (Contrast with endotoxin.)

Prokaryotes have amazingly diverse metabolic pathways

Prokaryotic archaea and bacteria outdo the eukaryotes in terms of metabolic diversity. Although they are much more diverse in size and shape, eukaryotes draw on fewer metabolic mechanisms for their energy needs. In fact, much of the eukaryotes' energy metabolism is carried out in organelles—mitochondria and chloroplasts—that are endosymbiotic descendants of bacteria. The long evolutionary history of prokaryotes, during which they have had time to explore a wide variety of habitats, has led to the extraordinary diversity of their metabolic “lifestyles”—their use or nonuse of oxygen, their energy sources, their sources of carbon atoms, and the materials they release as waste products.

ANAEROBIC VERSUS AEROBIC METABOLISM

Some prokaryotes can live only by anaerobic metabolism because oxygen is poisonous to them. These oxygen-sensitive organisms are called **obligate anaerobes**. Other prokaryotes can shift their metabolism between anaerobic and aerobic modes and are thus called **facultative anaerobes**. Many facultative anaerobes alternate between anaerobic metabolism (such as fermentation) and cellular respiration as conditions dictate. **Aerotolerant anaerobes** cannot conduct cellular respiration, but they are not damaged by oxygen when it is present. By definition, an anaerobe does not use oxygen as an electron acceptor for its respiration.

obligate anaerobe An anaerobic prokaryote that cannot survive exposure to O₂. (Compare with facultative anaerobe.)

facultative anaerobe A prokaryote that can shift its metabolism between anaerobic and aerobic modes depending on the presence or absence of O₂. Alternatively, facultative aerobe. (Compare with obligate anaerobe.)

aerotolerant anaerobe A prokaryote that does not require an oxygen atmosphere for survival, but which can live while exposed to O₂.

At the other extreme from the obligate anaerobes, some prokaryotes are **obligate aerobes**, unable to survive for extended periods in the *absence* of oxygen. They require oxygen for cellular respiration.

obligate aerobe An organism that requires an oxygen atmosphere to live.

NUTRITIONAL CATEGORIES

All living organisms face the same nutritional challenges: they must synthesize energy-rich compounds such as ATP to power their life-sustaining metabolic reactions, and they must obtain carbon atoms to build their own organic molecules. Biologists recognize four broad nutritional categories of organisms: photoautotrophs, photoheterotrophs, chemoautotrophs, and chemoheterotrophs. Prokaryotes are represented in all four groups ([Table 25.2](#)).

table 25.2 How Organisms Obtain Their Energy and Carbon		
Nutritional category	Energy source	Carbon source
Photoautotrophs (some bacteria, some eukaryotes)	Light	Carbon dioxide
Photoheterotrophs (some bacteria)	Light	Organic compounds
Chemoautotrophs (some bacteria, many prokaryotic archaea)	Inorganic substances	Carbon dioxide
Chemoheterotrophs (found in all three domains)	Usually organic compounds; sometimes inorganic substances	Organic compounds

Marshall and Warren set out to satisfy Koch’s postulates:

Test 1 The microorganism must be present in every case of the disease. Results: Biopsies from the stomachs of many patients revealed that the bacterium was always present if the stomach was inflamed or ulcerated.
Test 2 The microorganism must be cultured from a sick host. Results: The bacterium was isolated from biopsy material and eventually grown in culture media in the laboratory.
Test 3 The isolated and cultured bacteria must be able to induce the disease. Results: Marshall was examined and found to be free of bacteria and inflammation in his stomach. After drinking a pure culture of the bacterium, he developed stomach inflammation (gastritis).
Test 4 The bacteria must be recoverable from newly infected individuals. Results: Biopsy of Marshall's stomach 2 weeks after he ingested the bacteria revealed the presence of the bacterium, now christened <i>Helicobacter pylori</i> , in the inflamed tissue.

Conclusion Antibiotic treatment eliminated the bacteria and the inflammation in Marshall's stomach. The experiment was repeated on healthy volunteers, and many patients with gastric ulcers were cured with antibiotics. Thus Marshall and Warren demonstrated that the stomach inflammation leading to ulcers is caused by <i>H. pylori</i> infections in the stomach.
--

Photoautotrophs perform photosynthesis. They use light as their energy source and carbon dioxide (CO₂) as their carbon source. The cyanobacteria, like green plants and other photosynthetic eukaryotes, use chlorophyll a as their key photosynthetic pigment and produce oxygen gas (O₂) as a by-product of noncyclic electron transport.

photoautotroph An organism that obtains energy from light and carbon from carbon dioxide. (Contrast with chemoautotroph, chemoheterotroph, photoheterotroph.)

There are other photoautotrophs among the bacteria, but these organisms use bacteriochlorophyll as their key photosynthetic pigment, and they do not produce O₂. Instead, some of these photosynthesizers produce particles of pure sulfur, because hydrogen sulfide (H₂S), rather than H₂O, is their electron donor for photophosphorylation. Many proteobacteria fit into this category. Bacteriochlorophyll molecules absorb light of longer wavelengths than the chlorophyll molecules used by other photosynthesizing organisms. As a result, bacteria using this pigment can grow in water under fairly dense layers of algae, using light of wavelengths that are not absorbed by the algae (**Figure 25.21**).

Figure 25.21 Bacteriochlorophyll Absorbs Long-Wavelength Light The green alga *Ulva* contains chlorophyll, which absorbs no light of wavelengths longer than 750 nm. Purple sulfur bacteria, which contain bacteriochlorophyll, can conduct photosynthesis using longer infrared wavelengths. As a result, these bacteria can grow under layers of algae.

Photoheterotrophs use light as their energy source but must obtain their carbon atoms from organic compounds made by other organisms. Their “food” consists of organic compounds such as carbohydrates, fatty acids, and alcohols. For example, compounds released from plant roots (as in rice paddies) or from decomposing photosynthetic bacteria in hot springs are taken up by photoheterotrophs and metabolized to form building blocks for other compounds. Sunlight provides the ATP necessary for metabolism through photophosphorylation.

photoheterotroph An organism that obtains energy from light but must obtain its carbon

from organic compounds. (Contrast with chemoautotroph, chemoheterotroph, photoautotroph.)

Chemoautotrophs obtain their energy by oxidizing inorganic substances, and they use some of that energy to fix carbon. Some chemoautotrophs use reactions identical to those of the typical photosynthetic cycle, but others use alternative pathways for carbon fixation. Some bacteria oxidize ammonia or nitrite ions to form nitrate ions. Others oxidize hydrogen gas, hydrogen sulfide, sulfur, and other materials. Many prokaryotic archaea are chemoautotrophs.

chemoautotroph An organism that obtains energy by oxidizing inorganic substances, using some of that energy to fix carbon. Also known as a chemolithotroph. (Contrast with chemoheterotroph, photoautotroph, photoheterotroph.)

Finally, **chemoheterotrophs** obtain both energy and carbon atoms from one or more complex organic compounds that have been synthesized by other organisms. Most known bacteria and prokaryotic archaea are chemoheterotrophs—as are all animals and fungi and many protists.

chemoheterotroph An organism that must obtain both carbon and energy from organic substances. (Contrast with chemoautotroph, photoautotroph, photoheterotroph.)

Although most chemoheterotrophs rely on the breakdown of organic compounds for energy, some chemoheterotrophic prokaryotes obtain their energy by breaking down inorganic substances. Organisms that obtain energy from oxidizing inorganic substances (both chemoautotrophs as well as some chemoheterotrophs) are also known as lithotrophs (Greek, “rock consumers”).

Prokaryotes play important roles in element cycling

The metabolic diversity of the prokaryotes makes them key players in the cycles that keep elements moving through ecosystems. Many prokaryotes are decomposers: organisms that metabolize organic compounds in dead organic material and return the products to the environment as inorganic substances. Prokaryotes, along with fungi, return tremendous quantities of carbon to the atmosphere as carbon dioxide, thus carrying out a key step in the carbon cycle.

The key metabolic reactions of many prokaryotes involve nitrogen or sulfur. For example, some bacteria carry out respiratory electron transport without using oxygen as an electron acceptor. These organisms use oxidized inorganic ions such as nitrate, nitrite, or sulfate as electron acceptors. Examples include the **denitrifiers**, which release nitrogen to the atmosphere as nitrogen gas (N₂). These normally aerobic bacteria, mostly species of the genera *Bacillus* and *Pseudomonas*, use nitrate (NO₃⁻) as an electron acceptor in place of oxygen if they are kept under anaerobic conditions:

denitrifiers Bacteria that release nitrogen to the atmosphere as nitrogen gas (N₂).

Denitrifiers play a key role in the cycling of nitrogen through ecosystems. Without denitrifiers,

which convert nitrate ions back into nitrogen gas, all forms of nitrogen would leach from the soil and end up in lakes and oceans, making life on land much more difficult.

Nitrogen fixers convert atmospheric nitrogen gas into a chemical form (ammonia) that is usable by the nitrogen fixers themselves as well as by other organisms:

nitrogen fixers Organisms capable of fixing atmospheric N_2 to form NH_3 .

All organisms require nitrogen in order to build proteins, nucleic acids, and other important compounds. * **Nitrogen fixation** is thus vital to life as we know it. This all-important biochemical process is carried out by a wide variety of prokaryotic archaea and bacteria (including cyanobacteria) but by no eukaryotes, so we depend on these prokaryotes for our very existence.

Ammonia is oxidized to nitrate in soil and in seawater by chemoautotrophic bacteria called **nitrifiers**. Bacteria of two genera, *Nitrosomonas* and *Nitrosococcus*, convert ammonia (NH_3) to nitrite ions (NO_2^-), and *Nitrobacter* oxidize nitrite to nitrate (NO_3^-), the form of nitrogen most easily used by many plants. What do the nitrifiers get out of these reactions? Their metabolism is powered by the energy released by the oxidation of ammonia or nitrite. For example, by passing the electrons from nitrite through an electron transport system, *Nitrobacter* can make ATP and, using some of this ATP, can also make NADH. With this ATP and NADH, the bacterium can convert CO_2 and H_2O into glucose.

nitrifiers Prokaryotes that can convert ammonium into nitrate.

We have already seen the importance of the cyanobacteria in the cycling of oxygen: in ancient times, the oxygen generated by their photosynthesis converted Earth's atmosphere from an anaerobic to an aerobic environment. Other prokaryotes—both bacteria and archaea—contribute to the cycling of sulfur. Deep-sea hydrothermal vent ecosystems depend on chemoautotrophic prokaryotes that are incorporated into large communities of crabs, mollusks, and giant worms, all living at a depth of 2,500 m—below any hint of sunlight. These bacteria obtain energy by oxidizing hydrogen sulfide and other substances released in the near-boiling water flowing from volcanic vents in the ocean floor.

25.3 recap

Many prokaryotes are beneficial and even necessary to other forms of life. Most animals, including humans, depend on a complex community of prokaryotes—a microbiome—to maintain health, especially of the immune and digestive systems. Pathogenic bacteria are the direct causes of diseases.

learning outcomes

- Compare and contrast nitrogen fixers, denitrifiers, and nitrifiers.

1. How do biofilms form, and why are they of special interest to researchers?

- [2.](#) Why would elimination of all bacteria from a human gut be problematic from a health standpoint?
- [3.](#) Why is nitrogen metabolism in prokaryotes vital to other organisms?

Before moving on to discuss the diversity of eukaryotic life, it is appropriate to consider another category of life that includes some pathogens: the viruses. Although they are not cellular, viruses are numerically among the most abundant forms of life on Earth. Their effects on other organisms are enormous. Where did viruses come from, and how do they fit into the tree of life? Biologists are still working to answer these questions.

***connect the concepts** For descriptions of the role of nitrogen in plant nutrition and in the global nitrogen cycle, see [Key Concepts 35.4](#) and [57.4](#).

25.4 Viruses Have Evolved Many Times

Some biologists do not think of viruses as living organisms, primarily because they are not cellular and must depend on cellular organisms for basic life functions such as replication and metabolism. But viruses are derived from the cells of living organisms. They use the same essential forms of genetic information storage and transmission as do cellular organisms. Viruses infect all cellular forms of life—both prokaryotes and eukaryotes. They replicate, mutate, evolve, and interact with other organisms, often causing serious diseases in their hosts. Finally, viruses clearly evolve independently of other organisms, so it is almost impossible not to treat them as a part of life.

focus your learning

Several factors limit phylogenetic analysis of viruses.

Some DNA viruses may have evolved from reduced cellular organisms.

Viruses can be used to fight bacterial infections.

Viruses are abundant in many environments. In some freshwater and marine ecosystems, they can occur at densities of up to 10 million viruses per milliliter of water. Biologists estimate that there are approximately 10^{31} individual virus particles on Earth—about 1,000 times the number of cellular organisms on the planet. Viruses have an enormous effect on the ecology of the oceans. Every day, about one-half of the bacteria in the oceans are killed by viruses. Huge marine blooms of bacteria, such as the *Vibrio* bloom that produced the milky seas described at the opening of this chapter, do not last for long because viral blooms soon follow the initial bacterial bloom. As the viruses increase, they begin to kill bacteria faster than the bacteria can reproduce.

Although viruses are everywhere and play an important role in many ecosystems, many aspects of their ecology and evolution are still poorly known. For example, several factors make virus phylogeny difficult to resolve. The tiny size of many virus genomes restricts the phylogenetic analyses that can be conducted to relate viruses to cellular organisms. Their rapid mutation rate, which results in rapid evolution of virus genomes, tends to cloud evolutionary relationships over long periods. There are no known fossil viruses (viruses are too small and delicate to fossilize), so the paleontological record offers no clues to virus origins. Finally, viruses are highly diverse ([Figure 25.22](#)). Several lines of evidence support the hypothesis that viruses have evolved repeatedly within each of the major groups of life. The difficulty in resolving deep evolutionary relationships of viruses makes a phylogeny-based classification difficult. Instead, viruses are placed in one of several functionally similar groups on the basis of the structure of their genomes (for example, whether the genomes are composed of RNA or DNA, and are double- or single-stranded). Most of these defined groups are not thought to represent monophyletic taxa, however.

(A)

A negative-sense single-stranded RNA virus: The influenza A virus. This virus is responsible for seasonal influenza epidemics in humans. Surface view.

(B)

A positive-sense single-stranded RNA virus: Coronavirus of a type thought to be responsible for severe acute respiratory syndrome (SARS). Surface view.

(C)

An RNA retrovirus: One of the human immunodeficiency viruses (HIV) that causes AIDS. Cutaway view.

(D)

A double-stranded DNA virus: One of the many herpes viruses (Herpesviridae). Different herpes viruses are responsible for many human infections, including chicken pox, shingles, cold sores, and genital herpes (HSV1/2). Surface view.

(E)

A double-stranded DNA virus:

Bacteriophage T4. Viruses that infect bacteria are referred to as bacteriophage (or simply phage). T4 attaches leglike fibers to the outside of its host cell and injects its DNA into the cytoplasm through its "tail" (pink structure in this rendition).

(F)

A double-stranded DNA mimivirus: This *Acanthamoeba polyphaga* mimivirus (APMV) has a genome larger than some prokaryote genomes. Cutaway view.

Figure 25.22 Viruses Are Diverse Relatively small genomes and rapid evolutionary

rates make it difficult to reconstruct phylogenetic relationships among viruses. Instead, viruses are classified largely by general characteristics of their genomes. The images here are computer artists' reconstructions based on cryoelectron micrographs.

Many RNA viruses probably represent escaped genomic components of cellular life

Although viruses are now obligate parasites of cellular species, many viruses may once have been cellular components involved in basic cellular functions—that is, they may be “escaped” components of cellular life that now evolve independently of their hosts.

NEGATIVE-SENSE SINGLE-STRANDED RNA VIRUSES

An example of a likely “escaped” biochemical function comes from viruses with genomes composed of single-stranded [negative-sense RNA](#): RNA that is the complement of the mRNA needed for protein translation. Many of these negative-sense single-stranded RNA viruses have only a few genes, including one for an RNA-dependent RNA polymerase that allows them to make mRNA from their negative-sense RNA genome. Modern cellular organisms cannot generate mRNA in this manner (at least in the absence of viral infections), but scientists speculate that single-stranded RNA genomes may have been common in the distant past, before DNA became the primary molecule for genetic information storage.

negative-sense RNA A strand of RNA that is complementary to mRNA.
--

A self-replicating RNA polymerase gene that began to replicate independently of a cellular genome could conceivably acquire a few additional protein-coding genes through recombination with its host's DNA. If one or more of these genes were to foster the development of a protein coat, the virus might then survive outside the host and infect new hosts. It is believed that this scenario has been repeated many times independently across the tree of life, given that many of the negative-sense single-stranded RNA viruses that infect organisms from bacteria to humans are not closely related to one another. In other words, negative-sense single-stranded RNA viruses do not represent a distinct taxonomic group, but rather exemplify a particular process of cellular escape that probably happened many different times.

Familiar examples of negative-sense single-stranded RNA viruses include the viruses that cause measles, mumps, rabies, and influenza (see [Figure 25.22A](#)).

POSITIVE-SENSE SINGLE-STRANDED RNA VIRUSES

The genome of another type of single-stranded RNA virus is composed of positive-sense RNA. Positive-sense genomes are already set for translation; no replication of the genome to form a complement strand is needed before protein translation can take place. Positive-sense single-stranded RNA viruses (see [Figure 25.22B](#)) are the most abundant and diverse class of viruses. Most of the viruses that cause diseases in crop plants are members of this group. These viruses kill patches of cells in the leaves or stems of plants, leaving live cells amid a patchwork of discolored dead tissue (giving them the name of mosaic or mottle viruses; [Figure 25.23](#)). Other viruses in this group infect bacteria, fungi, and animals. Human diseases caused by positive-sense single-stranded RNA viruses include polio, hepatitis C, and the common cold. As is true of the other functionally defined groups of viruses, these viruses appear to have evolved multiple times across the tree of life from different groups of cellular ancestors.

Figure 25.23 Mosaic Viruses Are a Problem for Agriculture Mosaic, or “mottle,” viruses are the most diverse class of viruses. This leaf is from an apple tree infected with a mosaic virus.

RNA RETROVIRUSES

The RNA retroviruses are best known as the group that includes the human immunodeficiency viruses (HIV; see [Figure 25.22C](#)). Like the previous two categories of viruses, RNA retroviruses have genomes composed of single-stranded RNA and probably evolved as escaped cellular components.

Retroviruses are so named because reverse transcription is a necessary component of their reproduction. When the retrovirus enters the nucleus of its vertebrate host, viral reverse transcriptase produces complementary DNA (cDNA) from the viral RNA genome and then replicates the single-stranded cDNA to produce doublestranded DNA. Another virally encoded enzyme called integrase catalyzes the integration of the new piece of double-stranded viral DNA into the host's genome. The viral genome is then replicated along with the host cell's DNA. The integrated retroviral DNA is known as a **provirus**.

retrovirus An RNA virus that contains reverse transcriptase. Its RNA serves as a template for cDNA production, and the cDNA is integrated into a chromosome of the host cell.

provirus Double-stranded DNA made by a virus that is integrated into the host's chromosome and contains promoters that are recognized by the host cell's transcription apparatus.

Retroviruses are only known to infect vertebrates, although genomic elements that resemble portions of these viruses are a component of the genomes of a wide variety of organisms, including bacteria, plants, and many animals. Several retroviruses are associated with the development of various forms of cancer, as cells infected with these viruses are likely to undergo uncontrolled replication.

As retroviruses become incorporated into the genomes of their hosts, many become nonfunctional copies that are no longer expressed as functional viruses. These sequences may provide a record of ancient viral infections that plagued our ancestors. Humans, for example, carry about 100,000 fragments of **endogenous retroviruses** in our genome. These fragments make up about 8 percent of our DNA—a considerably larger fraction of our genome than the fraction that comprises all our protein-coding genes (about 1.2 percent of our genome).

endogenous retroviruses Retroviruses that have been incorporated into the host's genome.

DOUBLE-STRANDED RNA VIRUSES

Double-stranded RNA viruses may have evolved repeatedly from single-stranded RNA ancestors—or perhaps vice versa. These viruses, which are not closely related to one another, infect organisms from throughout the tree of life. Many plant diseases are caused by double-stranded RNA viruses. Other viruses of this type cause many cases of infant diarrhea in humans.

Media Clip 25.1 **Cyanobacteria W** www.Life11e.com/mc25.1

Some DNA viruses may have evolved from reduced cellular organisms

Another class of viruses is composed of viruses that have a double-stranded DNA genome (see [Figure 25.22D–F](#)). This group is also almost certainly polyphyletic (with many independent origins). Many of the common phage that infect bacteria are double-stranded DNA viruses, as are the viruses that cause smallpox and herpes in humans.

Some biologists think that at least some of the DNA viruses may represent highly reduced parasitic organisms that have lost their cellular structure as well as their ability to survive as free-living species. For example, the mimiviruses, which are some of the largest DNA viruses (see [Figure 25.22F](#)), have a genome in excess of a million base pairs of DNA that encode more than 900 proteins. This genome is similar in size to the genomes of many parasitic bacteria and about twice as large as the genome of the smallest bacteria ([Figure 25.24](#)). Phylogenetic analyses of these DNA viruses suggest that they have evolved repeatedly from cellular organisms. Furthermore, recombination among different viruses may have allowed the exchange of various genetic modules, further complicating the history and origins of these viruses.

Figure 25.24 Mimiviruses Have Genomes Similar in Size to Those of Many Parasitic Bacteria The genome of *Acanthamoeba polyphaga* mimivirus contains 1,181,404 base pairs and encompasses 911 protein-encoding genes. This observation is consistent with the hypothesis that this virus evolved from a parasitic

bacterium.

Q: Why do parasitic bacteria generally have smaller genomes and fewer protein-coding genes than free-living bacteria do?

Viruses can be used to fight bacterial infections

Although some viruses cause devastating diseases, other viruses have been used to fight disease. Most bacterial diseases are treated today with antibiotics. Antibiotics were first discovered in the 1930s, but they were not widely used to treat bacterial diseases until the 1940s. So antibiotics were not yet available during World War I, when bacterial infections plagued the battlefields. Battlefield wounds were often infected by bacteria, and in the absence of antibiotics, these infections often led to the loss of limbs and lives. While trying to find a way to combat this problem, a physician named Felix d'Herelle discovered the first evidence of viruses that attack bacteria. He named these viruses bacteriophage, or “eaters of bacteria.” Herelle extracted bacteriophage from the stool of infected patients. He then used these extracts to treat patients with deadly bacterial infections, including dysentery, cholera, and bubonic plague. This practice became known as **phage therapy**. After the war, phage therapy was widely used among the general public to treat bacterial infections of the skin and intestines.

phage therapy The therapeutic use of bacteriophages to treat pathogenic bacterial infections.

 Media Clip 25.3 **Bacteriophages Attack *E. coli*** www.Life11e.com/mc25.3

Phage therapy was mostly replaced by the use of antibiotics in the 1930s and 1940s as physicians grew concerned about treating patients with live viruses. Phage therapy continued to be used in the Soviet Union but largely disappeared from western medical practice. Today, however, many antibiotics are losing their effectiveness as bacterial pathogens evolve resistance to these drugs. Phage therapy is once again an active area of research, and it is likely that bacteriophage will become increasingly important as weapons against bacterial diseases. One advantage that bacteriophage may have over antibiotics is that, like bacteria, bacteriophage can evolve. As bacteria evolve resistance to a strain of bacteriophage, biologists can select for new strains of bacteriophage that retain their effectiveness against the pathogens. In this way, biologists are using their understanding of evolution to combat the problem of antibiotic-resistant bacteria.

25.4 recap

Viruses are highly diverse and appear to have evolved independently from many different cellular organisms within each of the major groups of life. Some viruses appear to have evolved from escaped components of cellular organisms, whereas other viruses may have evolved from parasitic cellular ancestors.

learning outcomes

You should be able to:

- Explain why viruses are difficult to place within the tree of life.
- Contrast the “escaped component” and “reduced parasite” hypotheses for the origin of viruses, and name major groups of viruses that best support each hypothesis.

- Explain why phage therapy is once again an active area of research.

1. How does the size of viral genomes limit phylogenetic analyses of viruses?
2. What are the two main hypotheses of viral origins?
3. How can viruses be used to treat some human diseases?

It appears that the enormous diversity of viruses is, at least in part, a result of their multiple origins from many different cellular organisms. It may be best to view viruses as spin-offs from the various branches on the tree of life—sometimes evolving independently of cellular genomes, sometimes recombining with them. One way to think of viruses is as the “bark” on the tree of life: certainly an important component all across the tree, but not quite like the main branches.

▶ investigatinglife

How and why do bacteria communicate with one another?

As we explored in Investigating Life: How Do Bacteria Communicate with One Another?, *Vibrio* bacteria send a chemical signal that is received by other bacteria. This signal is needed to produce bioluminescence. As *Vibrio* populations increase in density, the bioluminescence becomes strong enough to be visible to humans and other animals. But how is bioluminescence an advantage to the bacteria? What is its function?

Although marine *Vibrio* are able to live independently, they truly thrive inside the guts of fish and other marine animals. Inside a fish, *Vibrio* cells attach themselves to food particles, including phytoplankton, and are often expelled into the ocean as waste. How can they get back into their preferred environment? The bioluminescent glow produced by a dense colony of free-living *Vibrio* growing on phytoplankton attracts fish, which consume the phytoplankton and thus ingest the bacteria—which gets the bacteria into a new host fish.

The bioluminescent *Vibrio* described in Investigating Life: How Do Bacteria Communicate with One Another?, *V. fischeri*, have evolved a symbiotic relationship with the Hawaiian bobtail squid (*Euprymna scolopes*). Chemicals produced by a developing squid embryo specifically “recruit” *V. fischeri* from the surrounding seawater. The bacteria then preferentially migrate to specific tissues that develop into a bioluminescent “light organ” in the belly of the adult squid (Figure 25.25). The tiny (about 3 cm long) adult squid feed while floating near the sea surface at night. The soft glow produced by the bioluminescent bacteria mimics the moonlight above, so the squid are less visible to potential predators coming at them from below.

Vibrio fischeri live symbiotically inside the squid's light organ.

Figure 25.25 Bioluminescent Bacterial Symbionts *Vibrio* bacteria within the light organ

emit bioluminescence downward as the Hawaiian bobtail squid floats near the ocean surface to feed. At night, this allows the squid to blend in with moonlight or starlight rather than becoming a target for a predator from below.

Future directions

Research that helps biologists understand how bacteria communicate, and allows us to disrupt or change communication signals among bacteria, is critical for developing treatment strategies against persistent bacterial infections. In the case of health-threatening bacteria that produce problematic biofilms, researchers hope to find ways to block the quorum-sensing signals that lead to the production of the matrix polysaccharides, thus preventing pathogenic biofilms from forming.

Figure 25.25 Bioluminescent Bacterial Symbionts *Vibrio* bacteria within the light organ emit bioluminescence downward as the Hawaiian bobtail squid floats near the ocean surface to feed. At night, this allows the squid to blend in with moonlight or starlight rather than becoming a target for a predator from below.

► 25.1 Bacteria and Archaea Are the Two Primary Divisions of Life

- The earliest split in the tree of life is between Bacteria and Archaea. One lineage within the Archaea branch, the Eukarya, evolved specializations (such as a nucleus and membrane-enclosed organelles) that allowed them flourish. All organisms that are not eukaryotes are called prokaryotes. **Review** [Figure 25.1](#), [Table 25.1](#), [Animation 25.1](#)
- The cell walls of almost all bacteria contain [peptidoglycan](#), whereas the cell walls of prokaryotic archaea lack peptidoglycan.

peptidoglycan The cell wall material of many bacteria, consisting of a single enormous molecule that surrounds the entire cell.

- Some groups of bacteria can be differentiated using the [Gram stain](#). [Gram-negative bacteria](#) have a periplasmic space between the cell membrane and a distinct outer membrane. [Gram-positive bacteria](#) have a thick cell wall containing about five times as much peptidoglycan as a Gram-negative cell wall. **Review** [Figure 25.2](#), [Activity 25.1](#)

Gram stain A differential purple stain useful in characterizing bacteria. The peptidoglycan-rich cell walls of gram-positive bacteria stain purple; cell walls of gram-negative bacteria generally stain orange.

Gram-negative bacteria Bacteria that appear red when stained using the Gram-staining technique. These bacteria have an outer membrane outside the relatively thin peptidoglycan layer of the cell wall.

Gram-positive bacteria Bacteria that appear blue to purple when stained using the Gram-staining technique. These bacteria have an outer cell wall consisting of a thick layer of peptidoglycan.

- The three most common bacterial shapes are **cocci** (spheres), **bacilli** (rods), and **spirilla** (helices). **Review** [Figure 25.3](#)
- Phylogenetic classification of prokaryotes is now based principally on nucleotide sequences of their genomes, especially of the rRNA genes.
- Prokaryotes reproduce asexually by binary fission but may exchange genetic material. Reproduction and genetic exchange are not directly linked in prokaryotes.
- Although [lateral gene transfer](#) has occurred throughout prokaryotic evolutionary history, elucidation of many aspects of prokaryote phylogeny is still possible. **Review Focus: Key Figure 25.4**

lateral gene transfer The transfer of genes from one species to another, common among bacteria and archaea.

► 25.2 Prokaryote Diversity Reflects the Ancient Origins of Life

- Prokaryotes are the most numerous organisms on Earth, but only a small fraction of prokaryote diversity has been characterized to date.
- Several early-diverging groups of bacteria, such as **hadobacteria** and **hyperthermophilic bacteria**, live mostly in hot environments.
- The **firmicutes** include the **mycoplasmas**, which are among the smallest cellular organisms known.
- Some **actinobacteria** produce important antibiotics.
- The photosynthetic **cyanobacteria** release oxygen into the atmosphere. Cyanobacteria may live free as single cells or associate in multicellular colonies. **Review [Figure 25.9](#)**
- **Spirochetes** have unique structures called axial filaments that allow them to move in a corkscrew-like manner. **Review [Figure 25.10](#)**
- **Chlamydias** are tiny parasitic bacteria (0.2–1.5 μm in diameter) that live within the cells of other organisms. **Review [Figure 25.11](#)**
- The **proteobacteria** embrace the largest number of known species of bacteria.
- Prokaryotic archaea live in highly diverse environments and include many **extremophiles**. Most known crenarchaeotes are thermophilic, acidophilic, or both. Some euryarchaeotes are **methanogens**; **extreme halophiles** are also found among the euryarchaeotes. **Review [Figure 25.14](#)**

extremophiles Archaea and bacteria that live and thrive under conditions (e.g., extremely high temperatures) that would kill most organisms.

methanogens Methane-producing microbes.

extreme halophiles A group of euryarchaeotes that live exclusively in very salty environments.

- **[Ether linkages](#)** in the branched long hydrocarbon chains of the lipids that make up the cell membranes are characteristic of prokaryotic archaea. **Review [Figure 25.15](#)**

ether linkage The linkage of two hydrocarbons by an oxygen atom (HC—O—CH). Ether linkages are characteristic of the membrane lipids of the Archaea. (Contrast with ester linkage.)

► 25.3 Ecological Communities Depend on Prokaryotes

- Prokaryotes form complex communities, of which **[biofilms](#)** are one example. **Review [Figure 25.18](#)**

biofilm A community of microorganisms embedded in a polysaccharide matrix, forming a highly resistant coating on almost any moist surface.

- **[Microbiomes](#)** are the communities of prokaryotes that live in and on the bodies of multicellular organisms. These communities are often important to the health of the hosts, and changes to the microbiome may lead to serious health consequences. **Review [Figure 25.19](#)**

microbiome The diverse community of bacteria that lives on or within the body of an organism and is essential to bodily function.

- Communities of bacteria can communicate information about their density using chemical signals in a process known as [quorum sensing](#). **Review Investigating Life: How Do Bacteria Communicate with One Another?**

quorum sensing The use of chemical communication signals to trigger density-linked activities such as biofilm formation in prokaryotes.

- Prokaryotes inhabit the guts of many animals (including humans) and help them digest food.
- Koch's postulates establish the criteria by which an organism may be classified as a pathogen. Relatively few bacteria—and no prokaryotic archaea—are known to be pathogens. Review [Figure 25.20](#)
- Prokaryote metabolism is diverse. Some prokaryotes are anaerobic, others are aerobic, and still others can shift between these modes.
- prokaryotes fall into four broad nutritional categories: photoautotrophs, photoheterotrophs, chemoautotrophs, and chemoheterotrophs. Review [Table 25.2](#)
- prokaryotes play key roles in the cycling of elements such as nitrogen, oxygen, sulfur, and carbon.
- Some prokaryotes metabolize sulfur or nitrogen. Nitrogen fixers convert nitrogen gas into a form that organisms can metabolize. Nitrifiers convert that nitrogen into forms that can be used by plants, and denitrifiers return nitrogen to the atmosphere.

► 25.4 Viruses Have Evolved Many Times

- Viruses have evolved many times from many different groups of cellular organisms. They are placed in groups according to the structure of their genomes, but these groups are not thought to represent monophyletic taxa. Review [Figure 25.22](#)
- Some viruses are probably derived from escaped components of cellular organisms; others are thought to have evolved as highly reduced parasites. Review [Figure 25.24](#)
- Endogenous retroviruses can represent a substantial component of vertebrate genomes (8% in the case of the human genome).
- Viruses can be used to fight bacterial infections in a process known as phage therapy.

► Apply What You've Learned

Review

3.1 Some groups of bacteria can be distinguished based on the Gram stain.

3.1 Prokaryotes differ with respect to oxygen metabolism.

3.1 Prokaryotes play important roles in nitrogen cycling.

Bacteria are increasingly used for a variety of purposes that range from treating medical conditions to mitigating toxic waste spills. Determining which bacterial species would be appropriate for a particular purpose requires the application of knowledge of the diverse phenotypic characteristics of these bacteria.

The table below lists the characteristics of four bacteria, *Clostridium novyi*, *Thermus aquaticus*, *Paracoccus denitrificans*, and *Trichodesmium thiebautii*. Use this information to address the questions that follow.

	C. novyi	T. aquaticus	P. denitrificans	T. thiebautii
Metabolism	Obligate anaerobic	Obligate aerobic	Facultative anaerobic	Facultative anaerobic
Gram status	Positive	Negative	Negative	Negative
Optimal temperature (°C)	10°–40°	50°–80°	5°–30°	10°–30°
Typical habitat	Terrestrial	Aquatic	Aquatic	Aquatic
Miscellaneous		Chemotroph	Denitrifier	Nitrogen fixer

Questions

1. The concentration of nitrates in a sample of municipal sewage water is well above acceptable levels. Which of these bacteria would be expected to be most appropriate for reducing nitrate concentrations? Explain your answer.
2. Because tumors often grow much faster than they can acquire blood supply, cancerous tumors can have large regions where oxygen concentrations are very low. These hypoxic conditions are generally not found elsewhere in the body. Biomedical researchers can take advantage of this unusual property to inject bacteria that would specifically target the tumor cells and have as little effect on the rest of the body as possible. Based on the information in the table, which bacterium would be expected to be most appropriate for this application? Explain your answer.
3. Adding small amounts of ammonium increased the productivity of an aquatic ecosystem, but the effect was short-lived. Based on that finding, which bacterium would most likely improve the productivity of the ecosystem?
4. The antibiotic vancomycin inhibits peptidoglycan synthesis in bacteria that have a thick cell wall with much peptidoglycan. Which bacterium would most likely be sensitive to this antibiotic? Explain your answer.

investigatinglife

Predicting Toxic Red Tides

In summer 2005, a devastating red tide crippled the shellfish industry along the Atlantic coast of North America from Canada to Massachusetts. This red tide was produced by a bloom of dinoflagellates of the genus *Alexandrium*. These protists produce a powerful toxin that accumulates in clams, mussels, and oysters. A person who eats a mollusk contaminated with the toxin can experience a syndrome known as paralytic shellfish poisoning. Many people were sickened by eating mollusks that were harvested before the problem was diagnosed, and losses to the shellfish industry in 2005 were estimated at \$50 million.

Several species of dinoflagellates produce toxic red tides in many parts of the world. Along the Gulf of Mexico, red tides caused by dinoflagellates of the genus *Karenia* produce a neurotoxin that affects the central nervous systems of fish, which become paralyzed and cannot respire effectively. Huge numbers of dead fish wash up on Gulf Coast beaches during a *Karenia* red tide. In addition, wave action can produce aerosols of the *Karenia* toxin, and these aerosols often cause asthma-like symptoms in humans on shore.

After the losses that resulted from the 2005 red tide, biologists at the Woods Hole Oceanographic Institution (WHOI) on Cape Cod began to monitor and model dinoflagellate populations off the New England coast. If biologists could accurately forecast future blooms, people in the area could be made aware of the problem in advance and adjust the shellfish harvest (and their eating habits) accordingly.

Biologists from WHOI monitored counts of dinoflagellates in the water and in seafloor sediments. They also monitored river runoff, water currents, water temperature and salinity, winds, and tides. An additional environmental factor was the “nor’easter” storms common along the New England coast. By correlating their measurements of these environmental factors with dinoflagellate counts, biologists produced a model that predicted growth of dinoflagellate populations.

In spring 2008, the WHOI team determined that all the factors were in place to produce another red tide like the one of 2005—if a nor’easter occurred to blow the dinoflagellates toward the coast. A nor’easter did occur at just the wrong time, and another red tide materialized in summer 2008, just as predicted. But this time, people were warned. Shellfish harvesters adjusted their harvest, and many fewer people were harmed by eating toxic mollusks.

Red tides are harmful, but how are dinoflagellates beneficial to marine ecosystems?

26.1 Eukaryotes Acquired Features from Both Archaea and Bacteria

We easily recognize trees, mushrooms, and insects as plants, fungi, and animals, respectively. But there is a dazzling assortment of other eukaryotic organisms—mostly microscopic—that do not fit into these three groups. Eukaryotes that are not plants, animals, or fungi have traditionally been called **protists**. But phylogenetic analyses reveal that many of the groups we commonly refer to as protists are not, in fact, closely related. Thus the term “protist” does not describe a monophyletic group, but is a convenience term for “all the eukaryotes that are not plants, animals, or fungi.”

focus your learning

"Protists" is a convenient term for all eukaryotes that are not plants, animals, or fungi, but protists are not a monophyletic group.

An important step toward the modern eukaryotic cell was the loss of the cell wall.

Endosymbiosis was a key step in the evolution of modern eukaryotes.

All chloroplasts can be traced back to the same primary endosymbiosis event.

The unique characteristics of the eukaryotic cell lead scientists to conclude that the eukaryotes are monophyletic, and that a single eukaryotic ancestor diversified into the many different protist lineages as well as giving rise to the plants, fungi, and animals. As we saw in [Key Concept 25.1](#), eukaryotes are a specialized group of archaea that acquired a cell nucleus. The mitochondria and chloroplasts of eukaryotes, however, are clearly derived from bacterial lineages (see [Figure 25.1](#)).

Biologists have hypothesized that the origin of eukaryotes from a specialized archaean ancestor was followed by the endosymbioses with bacterial lineages that led to the origin of mitochondria and chloroplasts. Some biologists prefer to view the origin of eukaryotes as the fusion of lineages from the two prokaryote groups. This difference is largely a semantic one that hinges on the subjective point at which we deem the eukaryote lineage to have become definitively “eukaryotic.” In either case, we can make some reasonable inferences about the events that led to the evolution of a new cell type, bearing in mind that the environment underwent an enormous change—from low to high availability of free atmospheric oxygen—during the course of these events.

The modern eukaryotic cell arose in several steps

Several events were important in the origin of the modern eukaryotic cell (**Focus: Key Figure 26.1**):

Figure 26.1 Evolution of the Eukaryotic Cell The loss of a firm cell wall allowed the cell membrane to fold inward and create more surface area, which facilitated the evolution of larger cells. As cells grew larger, cytoskeletal complexity increased, and the cell became increasingly compartmentalized. Endosymbioses involving bacteria gave rise to mitochondria and (in photosynthetic eukaryotes) to chloroplasts.

Q: How could you use DNA sequencing and phylogenetic analysis to test the endosymbiotic origins hypothesis for mitochondria and chloroplasts?

The origin of a flexible cell surface

The origin of a cytoskeleton

The origin of a nuclear envelope, which enclosed a genome organized into chromosomes

The appearance of digestive vacuoles

The acquisition of mitochondria and chloroplasts via endosymbiosis

FLEXIBLE CELL SURFACE

We presume that ancient prokaryotic organisms, like most present-day prokaryotic cells, had firm cell walls. The first step toward the eukaryotic condition was the loss of the cell wall by a prokaryotic archaean. This wall-less condition occurs in some present-day prokaryotes.

Consider the possibilities open to a flexible cell without a firm wall, starting with cell size. As a cell grows larger, its surface area-to-volume ratio decreases (see [Figure 5.2](#)). Unless the surface area can be increased, the cell volume will reach an upper limit. If the cell's surface is flexible, however, it can fold inward and become more elaborate, creating more surface area for gas and nutrient exchange. With a surface flexible enough to allow infolding, the cell can exchange materials with its environment rapidly enough to sustain a larger volume and more rapid metabolism (see [Figure 26.1](#), steps 1-2). Furthermore, a flexible surface can pinch off bits of the environment, bringing them into the cell by endocytosis. These infoldings of the cell surface, which also exist in some modern prokaryotes, were important for the evolution of large eukaryotic cells.

CHANGES IN CELL STRUCTURE AND FUNCTION

Other early steps that were important for the evolution of the eukaryotic cell involved increased compartmentalization and complexity of the cell (see [Figure 26.1](#), steps 3-7):

The development of a more complex cytoskeleton

The formation of ribosome-studded internal membranes, some of which surrounded the DNA

The enclosure of the cell's DNA in a nucleus

The formation of a flagellum from microtubules of the cytoskeleton

The evolution of digestive vacuoles

Until a few years ago, biologists thought that cytoskeletons were restricted to eukaryotes. Improved imaging technology and molecular analyses have now revealed homologs of many cytoskeletal proteins in prokaryotes, so simple cytoskeletons evolved before the origin of eukaryotes. The cytoskeleton of a eukaryote, however, is much more developed and complex than that of a prokaryote. This greater development of microfilaments and microtubules supports the eukaryotic cell and allows it to manage changes in shape, to distribute daughter chromosomes, and to move materials from one part of its larger cell to other parts. In addition, the presence of microtubules in the cytoskeleton allowed some cells to develop the

characteristic eukaryotic flagellum.

The DNA of a prokaryotic cell is attached to a site on its cell membrane. If that region of the cell membrane were to fold into the cell, the first step would be taken toward the evolution of a nucleus, a primary feature of the eukaryotic cell. The nuclear envelope appeared early in the eukaryote lineage. The next step was probably phagocytosis—the ability to engulf and digest other cells.

ENDOSYMBIOSIS

At the same time the processes outlined above were taking place, cyanobacteria were generating O_2 as a product of photosynthesis. The increasing concentrations of O_2 in the oceans, and eventually in the atmosphere, had disastrous consequences for most organisms of the time, which were unable to tolerate the newly oxidizing environment. But some prokaryotes evolved strategies to use the increasing O_2 , and—fortunately for us—so did some of the new phagocytic eukaryotes.

At about this time, endosymbioses began to play a role in eukaryote evolution (see [Figure 26.1](#), steps 8-9). The theory of endosymbiosis proposes that certain organelles are the descendants of prokaryotes engulfed, but not digested, by ancient eukaryotic cells. One crucial event in the history of eukaryotes was the incorporation of a proteobacterium that evolved into the mitochondrion. Initially the new organelle's primary function was probably to detoxify O_2 by reducing it to water. Later this reduction became coupled with the formation of ATP in ***cellular respiration**. After this step, the essential eukaryotic cell was complete.

Photosynthetic eukaryotes are the result of yet another endosymbiotic step: the incorporation of a prokaryote related to today's cyanobacteria, which became the chloroplast.

Chloroplasts have been transferred among eukaryotes several times

Eukaryotes in several different groups possess chloroplasts, and groups with chloroplasts appear in several distantly related eukaryote clades. Some of these groups differ in the photosynthetic pigments their chloroplasts contain. And not all chloroplasts are limited to a pair of surrounding membranes—in some microbial eukaryotes, chloroplasts are surrounded by three or more membranes. We now view these observations as evidence of a remarkable series of endosymbioses. This conclusion is supported by extensive evidence from electron microscopy and nucleic acid sequence comparisons.

All chloroplasts trace their ancestry back to the engulfment of one cyanobacterium by a larger eukaryotic cell. This event, the step that first gave rise to the photosynthetic eukaryotes, is known as **primary endosymbiosis** ([Figure 26.2A](#)). The cyanobacterium, a Gram-negative bacterium, had both an inner and an outer membrane (see [Figure 25.2B](#)). Thus the original chloroplasts had two surrounding membranes: the inner and outer membranes of the cyanobacterium. Remnants of the peptidoglycan-containing cell wall of the bacterium are present in the form of a bit of peptidoglycan between the chloroplast membranes of glaucophytes, the first eukaryote group to branch off following primary endosymbiosis (as we will see in [Chapter 28](#)). Primary endosymbiosis also gave rise to the chloroplasts of the red algae, green algae, and land plants. The red algal chloroplast retains certain pigments of the original cyanobacterial endosymbiont that are absent in green algal chloroplasts.

primary endosymbiosis The engulfment of a cyanobacterium by a larger eukaryotic cell that gave rise to the first photosynthetic eukaryotes with chloroplasts.

(A) Primary endosymbiosis

(B) Secondary endosymbiosis

Figure 26.2 Endosymbiotic Events in the Evolution of Chloroplasts (A) A single instance of primary endosymbiosis ultimately gave rise to all of today's chloroplasts. (B) Secondary endo-symbiosis—the uptake and retention of a chloroplast-containing cell by another eukaryotic cell—took place several times, independently.

Almost all remaining photosynthetic eukaryotes are the result of additional rounds of endosymbiosis. For example, the photosynthetic euglenids derived their chloroplasts from **secondary endosymbiosis** (**Figure 26.2B**). Their ancestor took up a unicellular green alga, retaining its chloroplast and eventually losing the rest of the constituents of the alga. This history explains why the photosynthetic euglenids have the same photosynthetic pigments as the green algae and land plants. It also accounts for the third membrane of the euglenid chloroplast, which is derived from the euglenid's cell membrane (as a result of endocytosis). An additional round—**tertiary endosymbiosis**—occurred when a dinoflagellate apparently lost its chloroplast and took up another protist that had acquired its chloroplast through secondary endosymbiosis.

secondary endosymbiosis The engulfment of a photosynthetic eukaryote by another eukaryotic cell that gave rise to certain groups of photosynthetic eukaryotes (e.g., euglenids).

tertiary endosymbiosis The mechanism by which some eukaryotes acquired the capacity for photosynthesis; for example, a dinoflagellate that apparently lost its chloroplast became photosynthetic by engulfing another protist that had acquired a chloroplast through secondary endosymbiosis.

26.1 recap

The modern eukaryotic cell probably arose from an ancestral prokaryotic archaean in several steps, including the origin of a flexible cell surface and the enclosure of the genetic material in a nucleus. Later, endosymbioses of proteobacteria and cyanobacteria led to the origins of mitochondria and chloroplasts.

learning outcomes

You should be able to:

- Explain the use of the term "protist," and describe the relationships of major protist groups to other eukaryotes.
- Summarize the major changes that were important in the evolution of the eukaryotic cell.
- Explain how major changes in Earth's environment affected the evolution of the eukaryotic cell.
- Infer the history of genes based on whether their origins are nuclear, mitochondrial, or chloroplastic.

1. Why was the development of a flexible cell surface a key event for eukaryote evolution?
2. Explain how increased availability of atmospheric oxygen (O₂) could have influenced the evolution of the eukaryotic cell.

Background for Questions 3-4: Ribosomal RNA (rRNA) genes are present in the nuclear genome of eukaryotes. There are also rRNA genes in the genomes of mitochondria and chloroplasts. Therefore photosynthetic eukaryotes have three different sets of rRNA genes, which encode the structural RNA of three separate sets of ribosomes. The gene tree on the following page shows the evolutionary relationships among rRNA gene sequences isolated from the nuclear genomes of humans, yeast, and corn; from a

prokaryotic archaean (*Halobacterium*), a proteobacterium (*E. coli*), and a cyanobacterium (*Chlorobium*); and from the mitochondrial and chloroplast genomes of corn.

3. Why are the three rRNA genes of corn *not* one another's closest relatives?
4. Why is the relationship of the mitochondrial rRNA gene of corn to the rRNA gene of *E. coli* closer than it is to the nuclear rRNA genes of other eukaryotes? Can you explain the relationship of the rRNA gene from the chloroplast of corn to the rRNA gene of the cyanobacterium?
5. Explain why the term “protists” does not refer to a formal taxonomic group.

The features that eukaryotes gained from prokaryotic archaea and bacteria have allowed them to exploit many different environments. This led to the evolution of great diversity among eukaryotes, beginning with a radiation that started in the Precambrian.

***connect the concepts** You may wish to review the reactions of cellular respiration in [Key Concept 5.3](#).

26.2 Major Lineages of Eukaryotes Diversified in the Precambrian

Most eukaryotes can be placed in one of eight major clades that began to diversify about 1.5 billion years ago: alveolates, stramenopiles, rhizarians, excavates, plants, amoebozoans, fungi, and animals ([Figure 26.3](#)). Plants, fungi, and animals each have close protist relatives (such as the choanoflagellate relatives of animals), which we will discuss along with those major multicellular eukaryote groups in [Chapters 27-32](#).

Figure 26.3 Precambrian Divergence of Major Eukaryote Groups A phylogenetic tree shows a current hypothesis and estimated time line for the origin of the major groups of eukaryotes. The rapid divergence of major lineages between 1.5 and 1.4 billion years ago makes reconstruction of their precise relationships difficult. The major multicellular groups (tinted boxes) will be covered in subsequent chapters.

focus your learning

Multicellularity evolved dozens of times in the evolutionary history of eukaryotes.

Dinoflagellates are important primary producers of aquatic organic matter.

Apicomplexans possess an apical complex.

Ciliates are named for their numerous hair-like cilia.

Stramenopiles include the diatoms, the brown algae, and the oomycetes.

Brown algae are multicellular stramenopiles that have an abundance of fucoxanthin in their chloroplasts.

Rhizarians include the cercozoans, foraminiferans, and radiolarians.

A single amoeboid cell is the vegetative unit of the cellular slime mold.

Many protists are medically or economically important.

Each of the five major groups of protist eukaryotes covered in this chapter consists of organisms

with enormously diverse body forms and nutritional lifestyles. Some protists are motile, whereas others do not move. Some protists are photosynthetic, whereas others are heterotrophic. Most protists are unicellular, but some are multicellular. Most protists are microscopic, but a few are huge (giant kelps, for example, can grow to half the length of a football field). We refer to the unicellular species of protists as **microbial eukaryotes**, but keep in mind that there are large, multicellular protists as well.

Multicellularity has arisen dozens of times across the evolutionary history of eukaryotes. Four of the origins of multicellularity resulted in large organisms that are familiar to most people: plants, animals, fungi, and brown algae (the last are a group of stramenopiles). In addition, there are dozens of smaller and less familiar groups among the eukaryotes that include multicellular species. Recent experimental studies have shown that artificial selection for multicellularity can produce repeated, convergent evolution of multicellular forms over just a few months in some normally unicellular eukaryotic species. In addition, many unicellular species retain individual identities but nonetheless associate in large multicellular colonies. There is a near-continuum between fully integrated, multicellular organisms on the one hand and loosely integrated multicellular colonies of cells on the other. Biologists do not always agree on where to draw the line between the two.

Biologists used to classify protists largely on the basis of their life histories and reproductive features. In recent years, however, electron microscopy and gene sequencing have revealed many new patterns of evolutionary relatedness among these groups. Analyses of slowly evolving gene sequences are making it possible to explore evolutionary relationships among eukaryotes in ever greater detail and with greater confidence. Nonetheless, some substantial areas of uncertainty remain, and lateral gene transfer may complicate efforts to reconstruct the evolutionary history of protists (as was also true for prokaryotes; see [Key Concept 25.1](#)). Today we recognize great diversity among the many distantly related protist clades.

Alveolates have sacs under their cell membranes

Alveolates are so named because they possess sacs, called alveoli, just beneath their cell membranes, which may play a role in supporting the cell surface. All alveolates are unicellular, and most are photosynthetic, but they are diverse in body form. The alveolate groups we will consider in detail here are the dinoflagellates, apicomplexans, and ciliates.

alveolus (al ve' o lus) (plural: alveoli) [L. *alveus*: cavity] A small, baglike cavity, especially the blind sacs of the lung.

DINOFLAGELLATES

Most **dinoflagellates** are marine and photo-synthetic; they are important primary producers of organic matter in the oceans. Although fewer *species* of dinoflagellates live in freshwater,

individuals can be abundant in freshwater environments. The dinoflagellates are of great ecological, evolutionary, and morphological interest. A distinctive mixture of photosynthetic and accessory pigments gives their chloroplasts a golden brown color. Some dinoflagellate species cause red tides, as discussed at the start of this chapter. Other species are photosynthetic endosymbionts that live within the cells of other organisms, including invertebrate animals (such as corals; see Investigating Life: Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching?) and other marine protists (see [Figure 26.12A](#)). Still others are nonphotosynthetic and live as parasites within other marine organisms

Dinoflagellates have a distinctive appearance. They generally have two flagella, one in an equatorial groove around the cell, the other starting near the same point as the first and passing down a longitudinal groove before extending into the surrounding medium ([Figure 26.4](#)). Some dinoflagellates can take on different forms, including amoeboid ones, depending on environmental conditions. It has been claimed that the dinoflagellate *Pfiesteria piscicida* can occur in at least two dozen distinct forms, although this claim is highly controversial. In any case, this remarkable dinoflagellate, when present in large enough numbers, is harmful to fish and can both stun and feed on them.

Amphidiniopsis kofoidii

Figure 26.4 A Dinoflagellate The presence of two flagella is characteristic of many dinoflagellates, although these appendages are contained within deep grooves and thus are seldom visible. One flagellum lies within the equatorial groove and provides forward thrust and spin to the organism. The second flagellum originates in the longitudinal groove and acts like the rudder of a boat.

Media Clip 26.1 **A Dinoflagellate Shows Off Its Flagellum** www.Life11e.com/mc26.1

APICOMPLEXANS

The exclusively parasitic **apicomplexans** derive their name from the apical complex, a mass of organelles contained in the apical end (the tip) of the cell. These organelles help the apicomplexan invade its host's tissues. For example, the apical complex enables *Plasmodium*, the causative agent of malaria, to enter its target cells in the human body after transmission by a

mosquito.

Like many obligate parasites, apicomplexans have elaborate life cycles featuring asexual and sexual reproduction through a series of very dissimilar life stages (see [Figure 26.20](#)). In many species, these life stages are associated with two different types of host organisms, as is the case with *Plasmodium*. Another apicomplexan, *Toxoplasma*, alternates between cats and rats to complete its life cycle. A rat infected with *Toxoplasma* loses its fear of cats, which makes it more likely to be eaten by, and thus transfer the parasite to, a cat.

CILIATES

The [ciliates](#) are named for their numerous hairlike cilia, which are shorter than, but otherwise identical to, eukaryotic flagella. The ciliates are much more complex in body form than are most other unicellular eukaryotes ([Figure 26.5](#)). Their definitive characteristic is the possession of two types of nuclei (whose roles we will describe in [Key Concept 26.3](#) when we discuss protist reproduction). Almost all ciliates are heterotrophic, although a few contain photosynthetic endosymbionts.

cilia (sil' ee ah) (singular: cilium) [L. eyelashes] Hairlike organelle used for locomotion by many unicellular organisms and for moving water and mucus by many multicellular organisms. Generally shorter than flagella.

(A) *Paramecium* sp.

(B) *Didinium nasutum*

(C) *Trichodina* sp.

Figure 26.5 Diversity among the Ciliates (A) A free-swimming organism, this *Paramecium* belongs to a ciliate group whose members have many cilia of uniform length. (B) The barrel-shaped *Didinium nasutum* feeds on other ciliates, including *Paramecium*. Its cilia occur in two separate bands. (C) The parasite *Trichodina* creates suction with its ring of cilia that help attach it to the surface of a fish host.

Paramecium, a frequently studied ciliate genus, exemplifies the complex structure and behavior of ciliates ([Figure 26.6](#)). The slipper-shaped cell is covered by an elaborate pellicle, a structure composed principally of an outer membrane and an inner layer of closely packed, membrane-enclosed sacs (the alveoli) that surround the bases of the cilia. Defensive organelles called trichocysts are also present in the pellicle. In response to a threat, a microscopic explosion expels the trichocysts in a few milliseconds, and they emerge as sharp darts, driven forward at the tip of a long, expanding filament.

Figure 26.6 Anatomy of Paramecium *Paramecium*, with its many specialized organelles, exemplifies the complex body form of ciliates.

Activity 26.1 Anatomy of Paramecium www.Life11e.com/ac26.1

The cilia provide *Paramecium* with a form of locomotion that is generally more precise than locomotion by flagella. A *Paramecium* can coordinate the beating of its cilia to propel itself either forward or backward in a spiraling manner. It can also back off swiftly when it encounters a barrier or a negative stimulus. The coordination of ciliary beating is probably the result of a differential distribution of ion channels in the cell membrane near the two ends of the cell.

organisms living in fresh water are hypertonic to their environment. Many freshwater protists, including *Paramecium*, address this problem by means of specialized **contractile vacuoles** that excrete the excess water the organisms constantly take in by osmosis. The excess water collects in the contractile vacuoles, which then contract and expel the water from the cell.

contractile vacuole (kon trak' tul) A specialized vacuole that collects excess water taken in by osmosis, then contracts to expel the water from the cell.

Paramecium and many other protists engulf solid food by endocytosis, forming a **digestive vacuole** within which the food is digested (**Figure 26.7**). Smaller vesicles containing digested food pinch away from the digestive vacuole and enter the cytoplasm. These tiny vesicles provide a large surface area across which the products of digestion can be absorbed by the rest of the cell.

digestive vacuole In protists, an organelle specialized for digesting food ingested by endocytosis.

Figure 26.7 The Role of Vacuoles in Ciliate Digestion

Original Paper: Mast, S. O. 1947. The food-vacuole in *Paramecium*. *Biological Bulletin* 92: 31–72.

An acidic environment is known to aid digestion in many multicellular organisms. Do ciliates also use acid to obtain nutrients?

HYPOTHESIS▶ The digestive vacuoles of *Paramecium* produce an acidic environment that allows the organism to digest food particles.

METHOD

1. Feed *Paramecium* yeast cells stained with Congo red, a dye that is red at neutral or basic pH but turns green at acidic pH.
2. Under a light microscope, observe the formation and degradation of digestive vacuoles within the *Paramecium*. Note time and sequence of color (i.e., acid level) changes.

RESULTS

CONCLUSION▶ Some ciliates acidify digestive vacuoles to assist in the breakdown of food.

A morphological synapo-morphy of most **stra-menopiles** is the possession of rows of tubular hairs on the longer of their two flagella. Some stramenopiles lack flagella, but they are descended from ancestors that possessed flagella. The stramenopiles include the diatoms and the brown algae, which are photosynthetic, and the oomycetes, which are not.

DIATOMS

All of the **diatoms** are unicellular, although some species associate in filaments. Many have sufficient carotenoids in their chloroplasts to give them a yellow or brownish color. All of them synthesize carbohydrates and oils as photosynthetic storage products. Diatoms lack flagella except in male gametes.

Architectural magnificence on a microscopic scale is the hallmark of the diatoms. Almost all diatoms deposit silica (hydrated silicon dioxide) in their cell walls. The cell wall of a diatom is constructed in two pieces, with the top overlapping the bottom like the top of a petri dish. The silica-impregnated walls have intricate patterns unique to each species ([Figure 26.8](#)). Despite their remarkable morphological diversity, all diatoms are symmetrical—either bilaterally (with “right” and “left” halves) or radially (with the type of symmetry possessed by a circle).

Diatoms display either radial (circular) symmetry...

...or bilateral (left-right) symmetry.

25 μm

Figure 26.8 Diatom Diversity This bright-field micrograph illustrates the variety of species-specific forms found among the diatoms.

Media Clip 26.2 Diatoms in Action www.Life11e.com/mc26.2

Diatoms reproduce both sexually and asexually. Asexual reproduction by binary fission is somewhat constrained by the stiff cell wall. Both the top and bottom of the “petri dish” become tops of new “dishes” without changing appreciably in size. As a result, the new cell made from the former bottom is smaller than the parent cell. If this process continued indefinitely, one cell line would simply vanish, but sexual reproduction largely solves this potential problem. Gametes are formed, shed their cell walls, and fuse. The resulting zygote then grows substantially in size before a new cell wall is laid down.

Diatoms are found in all the oceans and are frequently present in great numbers. They are major photosynthetic producers in coastal waters (see [Key Concept 26.4](#)) and are among the dominant organisms in the dense “blooms” of phytoplankton that occasionally appear in the open ocean. Diatoms are also common in fresh water and even occur on the wet surfaces of terrestrial mosses.

BROWN ALGAE

The **brown algae** obtain their namesake color from the carotenoid fucoxanthin, which is abundant in their chloroplasts. The combination of this yellow-orange pigment with the green of chlorophylls *a* and *c* yields a brownish tinge. All brown algae are multicellular, and some are extremely large. Giant kelps such as those of the genus *Macrocystis* may be up to 60 m long.

Media Clip 26.3 A Kelp Forest www.Life11e.com/mc26.3

The brown algae are almost exclusively marine. They are composed either of branched filaments ([Figure 26.9A](#)) or of leaflike growths ([Figure 26.9B](#)). Some float in the open ocean; the most famous example is the genus *Sargassum*, which forms dense mats in the Sargasso Sea in the mid-Atlantic. Most brown algae, however, attach themselves to rocks near the shore. A few thrive only where they are regularly exposed to heavy surf. All of the attached forms develop a specialized structure, called a holdfast, that literally glues them to the rocks. The “glue” of the holdfast is alginic acid, a gummy polymer found in the walls of many brown algal cells. In addition to its function in holdfasts, alginic acid cements algal cells and filaments together. It is harvested and used by humans as an emulsifier in ice cream, cosmetics, and other products.

Holdfasts

Figure 26.9 Brown Algae (A) This seaweed illustrates the filamentous growth form of the brown algae. (B) Sea palms exemplify the leaflike growth form of brown algae. Sea palms and many other brown algal species are “glued” to the rocks by tough, branched structures called holdfasts that can withstand the pounding of the surf.

OOMYCETES

The **oomycetes** are the water molds and their terrestrial relatives. Water molds are filamentous and stationary. They are **absorptive heterotrophs**—that is, they secrete enzymes that digest large food molecules into smaller molecules that they can absorb. They are all aquatic and **saprobic**— meaning they feed on dead organic matter. If you have seen a whitish, cottony mold growing on dead fish or dead insects in water, it was probably a water mold of the common genus *Saprolegnia* (**Figure 26.10**).

absorptive heterotrophs Organisms (primarily fungi) that feed by **absorptive heterotrophy**, i.e., by secreting digestive enzymes into the environment to break down large food molecules, then absorbing the breakdown products.

3 mm

Figure 26.10 An Oomycete The filaments of a water mold radiate from the carcass of a beetle.

Some other oomycetes, such as the downy mildews, are terrestrial. Although most of the terrestrial oomycetes are harmless or helpful decomposers of dead matter, a few are plant parasites that attack crops such as avocados, grapes, and potatoes.

Oomycetes were once classified as fungi. However, we now know that their similarity to fungi is only superficial, and that the oomycetes are more distantly related to the fungi than are many other eukaryote groups, including humans (see **Figure 26.3**). For example, the cell walls of

oomycetes are typically made of cellulose, whereas those of fungi are made of chitin.

Rhizarians typically have long, thin pseudopods

The three primary groups of **rhizarians**—cercozoans, foraminiferans, and radiolarians—are unicellular and mostly aquatic. The rhizarians have contributed their shells to ocean sediments, some of which have become terrestrial features over the course of geological history.

CERCOZOANS

The **cercozoans** are a divergí group with many forms and habitats. Some are aquatic; others live in soil. One group of cercozoans possesses chloroplasts derived from a green alga by secondary endosymbiosis, and those chloroplasts contain a trace of the alga's nucleus.

FORAMINIFERANS

Some **foraminiferans** secrete external shells of calcium carbonate ([Figure 26.11](#)). These shells have accumulated over time to produce much of the world's limestone. Some foraminiferans live as plankton; others live on the seafloor. Living foraminiferans have been found 10,896 m down in the western Pacific's Challenger Deep—the deepest point in the world's oceans. At that depth, however, they cannot secrete normal shells because the surrounding water is too poor in calcium carbonate.

1 mm

Figure 26.11 Building Blocks of Limestone Some foraminiferans secrete calcium carbonate to form shells. The shells of different species have distinctive shapes. Over millions of years, the shells of foraminiferans have accumulated to form limestone deposits.

In living planktonic foraminiferans, long, threadlike, branched pseudopods extend through numerous microscopic apertures in the shell and interconnect to create a sticky, reticulated net, which the foraminiferans use to catch smaller plankton. In some foraminiferan species, the pseudopods provide locomotion.

RADIOLARIANS

Radiolarians are recognizable by their thin, stiff pseudopods, which are reinforced by microtubules ([Figure 26.12A](#)).

(A) *Amphilonche heteracantha*

(B) *Thyrsocyrtis* sp.

Figure 26.12 Radiolarians Exhibit Distinctive Pseudopods and Radial Symmetry

(A) The radiolarians are distinguished by their thin, stiff pseudopods and by their radial symmetry. The pigmentation seen at the center of this radiolarian's glassy endoskeleton is imparted by endosymbiotic dinoflagellates. (B) The endoskeleton secreted by a radiolarian.

These pseudopods greatly increase the surface area of the cell, and they help the cell stay

afloat in its marine environment.

Radiolarians also are immediately recognizable by their distinctive radial symmetry. Almost all radiolarian species secrete glassy endo-skeletons (internal skeletons). The skeletons of the different are as varied as snowflakes, and many have elaborate geometric designs ([Figure 26.12B](#)). A few radiolarians are among the largest of the unicellular eukaryotes, measuring several millimeters across.

Excavates began to diversify about 1.5 billion years ago

The **excavates** include a number of diverse groups that began to split from one another soon after the origin of eukaryotes. Several groups of excavates lack mitochondria, an absence that once led to the view that these groups might represent early-diverging eukaryotes that diversified before the evolution of mitochondria. However, the discovery of genes in the nucleus that are normally associated with mitochondria suggests that the absence of mitochondria is a derived condition in these organisms. In other words, ancestors of these excavate groups probably possessed mitochondria that were lost or reduced over the course of evolution. The existence of these organisms today shows that eukaryotic life is possible without mitochondria, at least among parasitic species.

DIPLOMONADS AND PARABASALIDS

The **diplomonads** and the **parabasalids** are unicellular and lack mitochondria (although they have reduced organelles that are derived from mitochondria). The parasitic *Giardia lamblia*, a diplomonad, causes the intestinal disease giardiasis. *Giardia* infections may result from contact with contaminated water. In the United States, such infections are common among hikers and campers using spring or stream water in recreational areas, as well as among children kept in close quarters (as in day-care centers). This tiny organism contains two nuclei bounded by nuclear envelopes, and it has a cytoskeleton and multiple flagella ([Figure 26.13A](#)).

(A) *Giardia muris*

(B) *Trichomonas vaginalis*

Figure 26.13 Some Excavate Groups Lack Mitochondria (A) *Giardia*, a diplomonad, has flagella and two nuclei. (B) *Trichomonas*, a parabasalid, has flagella and undulating membranes. Neither of these organisms possesses mitochondria.

In addition to flagella and a cytoskeleton, the parabasalids have undulating membranes that also contribute to the cell's locomotion. *Trichomonas vaginalis* (Figure 26.13B) is a parabasalid responsible for a sexually transmitted disease in humans. Infection of the male urethra, where it may occur without symptoms, is less common than infection of the vagina.

Figure 26.14 A Photosynthetic Euglenid In the *Euglena* species illustrated in this drawing, the second flagellum is rudimentary. Note that the primary flagellum originates at the anterior of the organism and trails toward its posterior.

HETEROLOBOSEANS

The amoeboid body form appears in several protist groups that are only distantly related to one another. The body forms of **heteroloboseans**, for example, resemble those of loboseans, an amoebozoan group that is not at all closely related to heteroloboseans (see the next section). Amoebas of the free-living heterolobosean genus *Naegleria*, some of which can enter the human body and cause a fatal disease of the nervous system, usually have a two-stage life cycle, in which one stage has amoeboid cells and the other flagellated cells.

EUGLENIDS AND KINETOPLASTIDS

The **euglenids** and **kineto-plastids** together constitute a clade of unicellular excavates with flagella. Their mitochondria contain distinctive disc-shaped cristae, and their flagella contain a crystalline rod not found in other organisms. They reproduce primarily asexually by binary fission.

The flagella of euglenids arise from a pocket at the anterior end of the cell. Spiraling strips of proteins under the cell membrane control the cell's shape. Some euglenids are photosynthetic. **Figure 26.14** depicts a typical cell of the genus *Euglena*. Like most other euglenids, this common freshwater organism has a complex cell structure. It propels itself through the water with the longer of its two flagella, which may also serve as an anchor to hold the organism in place. The second flagellum is often rudimentary.

 Media Clip 26.4 **Euglenids** www.Life11e.com/mc26.4

The euglenids have diverse nutritional requirements. Many species are always heterotrophic. Other species, including species of *Euglena*, are fully autotrophic in sunlight, using chloroplasts to synthesize organic compounds through photosynthesis. When kept in the dark, these euglenids lose their photosynthetic pigment and begin to feed exclusively on dissolved organic material in the water around them. A “bleached” *Euglena* resynthesizes its photosynthetic pigment when it is returned to the light and becomes autotrophic again. But *Euglena* cells treated with certain antibiotics or mutagens lose their photosynthetic pigment completely; neither they nor their descendants are ever autotrophs again. However, those descendants function well as heterotrophs.

The kinetoplastids are unicellular parasites with two flagella and a single, large mitochondrion. The mitochondrion contains a kineto-plast, a unique structure housing multiple circular DNA molecules and associated proteins. Some of these DNA molecules encode “guide proteins” that edit mRNA within the mitochondrion.

The kinetoplastids include several medically important species of pathogenic trypanosomes (**Table 26.1**). Some of these organisms are able to change their cell surface recognition molecules frequently, allowing them to evade our best attempts to kill them and thus eradicate the diseases they cause.

table 26.1 Three Pathogenic Trypanosomes			
	<i>Trypanosoma brucei</i>	<i>Trypanosoma cruzi</i>	<i>Leishmania major</i>
Human disease	Sleeping sickness	Chagas disease	Leishmaniasis
Insect vector	Tsetse fly	Assassin bugs (many species)	Sand fly
Vaccine or effective cure	None	None	None
Strategy for survival	Changes surface recognition molecules frequently	Causes changes in surface recognition molecules on host cell	Reduces effectiveness of macrophage hosts
Site in human body	Bloodstream; in final stages, attacks nerve tissue	Enters cells, especially muscle cells	Enters cells, primarily macrophages
Approximate number of deaths per year	7,000	11,000	63,000

Amoebozoans use lobe-shaped pseudopods for locomotion

Amoebozoans appear to have diverged from other eukaryotes about 1.5 billion years ago (see [Figure 26.3](#)). It is not yet clear whether they are more closely related to opisthokonts (which include fungi and animals) or to other major groups of eukaryotes.

The lobe-shaped pseudopods of amoebozoans ([Figure 26.15](#)) are a hallmark of the amoeboid body form. Amoebozoan pseudopods differ in form and function from the slender pseudopods of rhizarians. We consider three amoebozoan groups here: the lobose-ans and two groups known as slime molds.

Amoeba proteus

Figure 26.15 An Amoeba in Motion The flowing pseudopods of this “chaos amoeba” (a lobosean) are constantly changing shape as it moves and feeds.

LOBOSEANS

Loboseans are small amoebozoans that feed on other small organisms and particles of organic matter by phagocytosis, engulfing them with pseudopods. Many loboseans are adapted for life on the bottoms of lakes, ponds, and other bodies of water. Their creeping locomotion and their manner of engulfing food particles fit them for life close to a relatively rich supply of sedentary organisms or organic particles. Most loboseans exist as predators, parasites, or scavengers. Members of one group of loboseans, the testate amoebas, live inside shells. Some of these amoebas produce casings by gluing sand grains together ([Figure 26.16](#)). Other testate amoebas have shells secreted by the organism itself.

Nebela collaris

Figure 26.16 Life in a Glass House This testate amoeba has built a lightbulb-shaped shell, or test, by gluing sand grains together. Its pseudopods extend through the single aperture in the test.

PLASMODIAL SLIME MOLDS

If the nucleus of an amoeba began rapid mitotic division, accompanied by a tremendous increase in cytoplasm and organelles, but no cytokinesis, the resulting organism would resemble the multinucleate mass of a **plasmodial slime mold**. During its vegetative (feeding, nonreproductive) stage, a plasmodial slime mold is a wall-less mass of cytoplasm with numerous diploid nuclei. This mass streams very slowly over its substrate in a remarkable

network of strands called a plasmodium ([Figure 26.17A](#)). The plasmodium is an example of a **coenocyte**: many nuclei enclosed in a single cell membrane. The outer cytoplasm of the plasmodium (closest to the environment) is normally less fluid than the interior cytoplasm and thus provides some structural rigidity.

(A) A plasmodium

(B) Fruiting structures of a plasmodial slime mold

Figure 26.17 A Plasmodial Slime Mold (A) The plasmodial form of the slime mold *Hemitrichia serpula* covers rocks, decaying logs, and other objects as it engulfs bacteria and other food items; it is also responsible for the organism's common name of "pretzel mold." (B) Fruiting structures of *Hemitrichia*.

Media Clip 26.6 **Plasmodial Slime Mold Growth** www.Life11e.com/mc26.6

Plasmodial slime molds provide a dramatic example of movement by **cytoplasmic streaming**. The outer cytoplasm of the plasmodium becomes more fluid in places, and cytoplasm rushes into those areas, stretching the plasmodium. This streaming reverses its direction every few minutes as cytoplasm rushes into a new area and drains away from a previous one, moving the plasmodium over its substrate. Sometimes an entire wave of plasmodium moves across a surface, leaving strands behind. Microfilaments and a contractile protein called myxomyosin interact to produce the streaming movement. As it moves, the plasmodium engulfs food particles by endocytosis—predominantly bacteria, yeasts, spores of fungi, and other small organisms as well as decaying animal and plant remains.

cytoplasmic streaming The flow of cytoplasm around fungal and plant cells.

A plasmodial slime mold can grow almost indefinitely in its plas-modial stage as long as the food supply is adequate and other conditions, such as moisture and pH, are favorable. If conditions become unfavorable, however, one of two things can happen. First, the plasmodium can form an irregular mass of hardened cell-like components. This resting structure rapidly becomes a plasmodium again when favorable conditions are restored.

Alternatively, the plasmodium can transform itself into spore-bearing fruiting structures ([Figure 26.17B](#)). These stalked or branched structures rise from heaped masses of plasmodium. They derive their rigidity from walls that form and thicken between their nuclei. Diploid nuclei of the plasmodium divide by meiosis as the fruiting structure develops. One or more knobs, called sporangia, develop on the end of the stalk. Within a sporangium, haploid nuclei become surrounded by walls to form spores. Eventually, as the fruiting structure dries, it sheds its spores.

The spores germinate into wall-less, haploid cells called swarm cells, which can either divide mitotically to produce more haploid swarm cells or function as gametes. Swarm cells can live as separate individual cells that move by means of flagella or pseudopods, or they can become walled and resistant resting cysts when conditions are unfavorable; when conditions improve again, the cysts release swarm cells. Two swarm cells can also fuse to form a diploid zygote, which divides by mitosis (but without a wall forming between the nuclei) and thus forms a new coenocytic plasmodium.

CELLULAR SLIME MOLDS

Whereas the plasmodium is the basic vegetative unit of the plasmodial slime molds, a single amoeboid cell is the vegetative unit of the [cellular slime molds](#) ([Figure 26.18](#)). Cells called myxamoebas, which have single haploid nuclei, swarm together as they engulf bacteria and other food particles by endocytosis and reproduce by mitosis and fission. This simple life cycle stage, consisting of swarms of independent, isolated cells, can persist indefinitely as long as food and moisture are available.

cell The simplest structural unit of a living organism. In multicellular organisms, many individual cells serve as the building blocks of tissues and organs.

Figure 26.18 A Cellular Slime Mold This composite micrograph shows the life cycle of the slime mold *Dictyostelium*.

Media Clip 26.7 **Cellular Slime Mold Aggregation** www.Life11e.com/mc26.7

When conditions become unfavorable, the cellular slime molds form fruiting structures, as do their plasmodial counterparts. The individual myxamoebas aggregate into a mass called a slug or **pseu-doplasmodium**. Unlike the true plasmodium of the plasmodial slime molds, this structure is not simply a giant sheet of cytoplasm with many nuclei; the individual myxamoebas within the slug retain their cell membranes and therefore their identity.

A slug may migrate over a substrate for several hours before becoming motionless and reorganizing to construct a delicate, stalked fruiting structure. Cells at the top of the fruiting structure develop into thick-walled spores, which are eventually released. Later, under favorable conditions, the spores germinate, releasing myxamoebas.

The cycle from myxamoebas through slug and spores to new myxamoebas is asexual. Cellular slime molds also have a sexual cycle, in which two myxamoebas fuse. The product of this fusion develops into a spherical structure that ultimately germinates, releasing new haploid myxamoebas.

26.2 recap

The major lineages of eukaryotes began to diverge about 1.5 billion years ago. Major groups of eukaryotes are highly diverse in their habitat, nutrition, locomotion, and body form. Many protists are photosynthetic autotrophs, but heterotrophic lineages have evolved repeatedly. Although most protists are unicellular, multicellularity has arisen independently many times.

learning outcomes

You should be able to:

- Identify stramenophiles on the basis of phenotypic characteristics.
- Distinguish among the major groups of eukaryotes.
- Justify the position that multicellularity is relatively easy to evolve.
- Explain why protists are important to our medical and economic concerns.

-
1. For each pair of groups below, describe how you could recognize members of the two groups and differentiate them from one another. Then describe features that the two groups in each pair share.
 - a. Foraminiferans and radiolarians
 - b. Ciliates and dinoflagellates
 - c. Diatoms and brown algae
 - d. Plasmodial slime molds and cellular slime molds
 2. The fossil record of eukaryotes from the Precambrian is poor compared with that from the Cambrian and later geological periods, even though eukaryotes were diversifying for the last billion years of the Precambrian. Can you think of some reasons why the eukaryotic fossil record became more extensive in the Cambrian?
 3. Give examples of alveolates, stramenopiles, and excavates that are important for medical or culinary reasons.

The ancient origins of the major eukaryote lineages and the adaptation of these lineages to a wide variety of lifestyles and environments resulted in enormous protist diversity. It is not surprising, then, that reproductive modes among protists are also highly diverse.

26.3 Protists Reproduce Sexually and Asexually

Although most protists engage in both asexual and sexual reproduction, sexual reproduction has yet to be observed in some groups. In some protists, as in all prokaryotes, the acts of sex and reproduction are not directly linked.

focus your learning

Ciliate conjugation is a sexual process but is not a reproductive process.

Organisms that engage in alternation of generations have distinct multicellular haploid and diploid phases.

Several asexual reproductive processes have been observed among the protists:

The equal splitting of one cell into two by mitosis followed by cytokinesis

The splitting of one cell into multiple (i.e., more than two) cells

The outgrowth of a new cell from the surface of an old one (known as [budding](#))

budding Asexual reproduction in which a more or less complete new organism grows from the body of the parent organism, eventually detaching itself.

The formation of specialized cells (spores) that are capable of developing into new individuals (known as [sporulation](#))

sporulation The formation of spores, or resting stages.

Asexual reproduction results in offspring that are genetically nearly identical to their parents (they differ only by new mutations that may arise during DNA replication). Such asexually reproduced groups of nearly identical organisms are known as [clonal lineages](#).

clonal lineages Asexually reproduced groups of nearly identical organisms.

Sexual reproduction among the protists takes various forms. In some protists, as in animals, the gametes are the only haploid cells. In others, the zygote is the only diploid cell. In still others, both diploid and haploid cells undergo mitosis, giving rise to alternating multicellular diploid and haploid life stages.

Some protists reproduce without sex and have sex without reproduction

As noted in [Key Concept 26.2](#), members of the genus *Paramecium* are ciliates, which commonly have two types of nuclei in a single cell (one macronucleus and from one to several micronuclei; see [Figure 26.6](#)). The micronuclei are typical eukaryotic nuclei and are essential for genetic recombination. Each macronucleus contains many copies of the genetic information, packaged

in units containing only a few genes each. The macronuclear DNA is transcribed and translated to regulate the life of the cell.

When paramecia reproduce asexually, all of the nuclei are copied before the cell divides. Paramecia (and many other protists) also have an elaborate sexual behavior called **conjugation**, in which two individuals line up tightly against each other and fuse in the oral groove region of the body. Nuclear material is extensively reorganized and exchanged over the next several hours (**Figure 26.19**). Each cell ends up with two haploid micronuclei, one of its own and one from the other cell, which fuse to form a new diploid micronucleus. A new macronucleus develops from that micronucleus through a series of dramatic chromosomal rearrangements. The exchange of nuclei is fully reciprocal: each of the two paramecia gives and receives an equal amount of DNA. The two organisms then separate and go their own ways, each equipped with new combinations of alleles.

conjugation (kon ju gay' shun) [L. *conjugare*: yoke together] (1) A process by which DNA is passed from one cell to another through a conjugation tube, as in bacteria. (2) A nonreproductive sexual process by which *Paramecium* and other ciliates exchange genetic material.

Figure 26.19 Conjugation in Paramecia The exchange of micronuclei by two conjugating *Paramecium* individuals results in genetic recombination. After conjugation, the cells separate and continue their lives as two individuals.

Q: Why is conjugation considered sex without reproduction?

Conjugation in *Paramecium* is a sexual process of genetic recombination, but it is not a reproductive process. Two cells begin conjugation and two cells are there at the end, so no new cells are created. As a rule, each asexual clone of paramecia must conjugate periodically. Experiments have shown that if some species are not permitted to conjugate, the clones can live through only about 350 cell divisions before dying out.

Some protist life cycles feature alternation of generations

Alternation of generations is a type of life cycle found in many multicellular protists, all land plants, and some fungi (see **Figure 27.6**). A multicellular, diploid, spore-producing organism gives rise to a multicellular, haploid, gamete-producing organism. When two haploid gametes fuse, a diploid organism is produced. The haploid organism, the diploid organism, or both may also reproduce asexually. Note that alternation of generations is distinct from the familiar reproductive system of animals, in which the only haploid stages are unicellular gametes produced by multicellular, diploid adults.

alternation of generations The succession of multicellular haploid and diploid phases in

some sexually reproducing organisms, notably plants.

The two alternating (spore-producing and gamete-producing) generations differ genetically (one has diploid cells, the other haploid cells), but they may or may not differ morphologically. In **heteromorphic** alternation of generations, the two generations differ morphologically; in **isomorphic** alternation of generations, they do not. Examples of both heteromorphic and isomorphic alternation of generations are found among the brown algae.

isomorphic (eye so more' fik) [Gk. *isos*: equal + *morphe*: form] Having the same form or appearance, as when the haploid and diploid life stages of an organism appear identical. (Contrast with heteromorphic.)

The gamete-producing generation does not produce gametes by meiosis because the gamete-producing organism is already haploid. Instead, specialized cells of the diploid spore-producing organism, called **sporocytes**, divide meiotically to produce four haploid spores. The spores may eventually germinate and divide mitotically to produce the multicellular haploid generation, which then produces gametes by mitosis and cytokinesis.

Gametes, unlike spores, can produce new organisms only by fusing with other gametes. The fusion of two gametes produces a diploid zygote, which then undergoes mitotic divisions to produce a diploid organism. The diploid organism's sporocytes then undergo meiosis and produce haploid spores, starting the cycle anew.

26.3 recap

Protists reproduce both asexually and sexually, although sex occurs independently of reproduction in some species. Some multicellular protists exhibit alternation of generations, alternating between multicellular haploid and diploid life stages.

learning outcomes

You should be able to:

- Distinguish between sex (in the sense of exchange of genes leading to genetic recombination) and reproduction.
- Predict the evolutionary consequences of reproduction without sex for long periods of time.
- Apply the definition of “alternation of generations” to determine whether a species is undergoing the process.

1. Why is conjugation between paramecia considered a sexual process but not a reproductive process?
2. Why do you think paramecia that are not allowed to conjugate begin to die out after about 350 rounds of asexual reproduction?
3. Although most diploid animals have haploid stages (e.g., eggs and sperm), their life cycles are not considered an example of alternation of generations. Why not?

Given the diversity of protists and of the environments in which they live, it is not surprising that they influence their environments in numerous ways.

26.4 Protists Are Critical Components of Many Ecosystems

Some protists are food for marine animals, while others poison those animals. Some are packaged as nutritional supplements for humans, and some are human pathogens. The remains of some form the sands of many modern beaches, and others are a major source of the oil that sometimes fouls those beaches.

focus your learning

Plasmodium is a specialized group of malaria-causing apicomplexans that are transmitted by mosquitoes.

The overproduction of some diatoms and dinoflagellates can result in deadly red tides.

Corals rely on dinoflagellate endosymbionts to obtain food.

Diatomaceous earth comes from the decomposition of diatoms.

Phytoplankton are primary producers

A single protist clade, the diatoms, performs about one-fifth of all photosynthetic carbon fixation on Earth—about the same amount as all of Earth's rainforests. These spectacular unicellular organisms (see [Figure 26.8](#)) are the predominant component of the oceanic phytoplankton, but the phytoplankton include many other protists that also contribute heavily to global photosynthesis. Like green plants on land, these “floating photosynthesizers” are the gateway for energy from the sun into the rest of the living world; in other words, they are **primary producers**. These autotrophs are eaten by heterotrophs, including animals and many other protists. Those consumers are, in turn, eaten by other consumers. Most aquatic heterotrophs (with the exception of some species in the deep sea) depend on photosynthesis performed by phytoplankton.

primary producer A photosynthetic or chemosynthetic organism that synthesizes complex organic molecules from simple inorganic ones.

Some microbial eukaryotes are deadly

Some microbial eukaryotes are pathogens that cause serious diseases in humans and other vertebrates. The best-known pathogenic protists are members of the genus *Plasmodium*, a highly specialized group of apicomplexans that spend part of their life cycle as parasites in human red blood cells, where they are the cause of malaria. In terms of the number of people affected, malaria is one of the world's three most serious infectious diseases: it infects more than 350 million people, and kills nearly a million people, each year. On average, about two people die from malaria every minute of every day—most of them in sub-Saharan Africa, although malaria occurs in more than 100 countries.

Mosquitoes of the genus *Anopheles* transmit *Plasmodium* to humans. The parasites enter the human circulatory system when an infected female *Anopheles* mosquito penetrates the skin in search of blood. The parasites find their way to cells in the liver and the lymphatic system,

change their form, multiply, and reenter the bloodstream, where they invade red blood cells.

The parasites multiply inside the red blood cells, which then lyse (burst), releasing new swarms of parasites. These episodes of bursting red blood cells coincide with the primary symptoms of malaria, which include fever, shivering, vomiting, joint pains, and convulsions. If another *Anopheles* bites the victim, the mosquito takes in *Plasmodium* cells along with blood. Some of the ingested cells develop into gametes that unite in the mosquito, forming zygotes. The zygotes lodge in the mosquito's gut, divide several times, and move into its salivary glands, from which they can be passed on to another human host. Thus *Plasmodium* is an extracellular parasite in the mosquito vector and an intracellular parasite in the human host (**Figure 26.20**). Such an organism—that is, a parasite that requires more than one host—is said to have a **complex life cycle**.

Figure 26.20 Life Cycle of the Malarial Parasite (A) Like many parasitic species, the apicomplexan *Plasmodium falciparum* has a complex life cycle, part of which is spent in mosquitoes of the genus *Anopheles* and part in humans. The sexual phase (gamete fusion) of this life cycle takes place in the insect, and the zygote is the only diploid stage. **(B)** Encysted *Plasmodium* zygotes (artificially colored blue) cover the stomach wall of a mosquito. Invasive sporozoites will hatch from the cysts and be transmitted to a human, in whom the parasite causes malaria.

Animation 26.3 Life Cycle of the Malarial Parasite www.Life11e.com/a26.3

complex life cycle In reference to parasitic species, a life cycle that requires more than one host to complete.

Plasmodium has proved to be a singularly difficult pathogen to attack. The complex *Plasmodium* life cycle is best broken by the removal of stagnant water, in which mosquitoes breed. Using insecticides to reduce the *Anopheles* population can also be effective, but the benefits must be weighed against the ecological, economic, and health risks posed by the insecticides themselves.

Even some of the phytoplankton that are such important primary producers can be deadly, as described in this chapter's opening story. Some diatoms and dinoflagellates reproduce in enormous numbers when environmental conditions are favorable for their growth. In the resulting red tides, the concentration of dinoflagellates may reach 60 million per liter of ocean water and produce potent nerve toxins that harm or kill many vertebrates, especially fish.

Some microbial eukaryotes are endosymbionts

Endosymbiosis is common among the microbial eukaryotes, many of which live within the cells of animals. Many radiolarians harbor photosynthetic endosymbionts (see [Figure 26.12A](#)). As a result, these radiolarians, which are not photosynthetic themselves, appear greenish or golden, depending on the type of endosymbiont they contain. This arrangement is often mutually beneficial: the radiolarian can make use of the carbon compounds produced by its photosynthetic guest, and the guest may in turn make use of metabolites made by the host or receive physical protection. In some cases, the guest is exploited for its photosynthetic products while receiving little or no benefit itself.

Dinoflagellates are also common endosymbionts and can be found in both animals and other protists. Most, but not all, dinoflagellate endosymbionts are photosynthetic. Some dinoflagellates live endosymbiotically in the cells of corals, contributing the products of their photosynthesis to the partnership. Their importance to the corals is demonstrated when the dinoflagellates die or are expelled by the corals as a result of changing environmental conditions such as rising water temperatures or increased water turbidity. This phenomenon is known as [coral bleaching](#). Unless the corals can acquire new endosymbionts, they are ultimately damaged or destroyed as a result of their reduced food supply (**Investigating Life: Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching?**).

coral bleaching The loss of color in coral colonies, usually because of the loss or decline of symbiotic zooxanthellae.

We rely on the remains of ancient marine protists

Diatoms are lovely to look at, but their importance to us goes far beyond aesthetics, and even beyond their role as primary producers. Diatoms store oil as an energy reserve and to keep themselves afloat at the correct depth in the ocean. Over millions of years, diatoms have died and sunk to the ocean floor, where they have undergone chemical changes. In this way, they have become a major source of petroleum and natural gas, two of our most important energy supplies and political concerns.

Because the silica-containing cell walls of dead diatoms resist decomposition, some sedimentary rocks are composed almost entirely of diatom skeletons that sank to the seafloor over time. Diatomaceous earth, which is obtained from such rocks, has many industrial uses, such as insulation, filtration, and metal polishing. It has also been used as an "Earth-friendly" insecticide that clogs the tracheae (breathing structures) of insects.

Other ancient marine protists have also contributed to today's world. Some foraminiferans, as we have seen, secrete shells of calcium carbonate. After they reproduce (by mitosis and cytokinesis), the daughter cells abandon the parent shell and make new shells of their own. The discarded shells of ancient foraminiferans make up extensive limestone deposits in various parts of the world, forming a layer hundreds to thousands of meters deep over millions of square

kilometers of ocean bottom. Foraminiferan shells also make up much of the sand of some beaches. A single gram of such sand may contain as many as 50,000 foraminiferan shells and shell fragments.

The shells of individual foraminiferans are easily preserved as fossils in marine sediments. Each geological period has a distinctive assemblage of foraminiferan species. Because the shells of foraminiferan species have distinctive shapes (see [Figure 26.11](#)) and because they are so abundant, the remains of foraminiferans are especially valuable in classifying and dating sedimentary rocks. In addition, analyses of the chemical makeup of foraminiferan shells can be used to estimate the global temperatures prevalent at the time when the shells were formed.

26.4 recap

Protists have many effects, both positive and negative, on their environment. Some species are important primary producers, many are endosymbionts, and some are pathogens. Protists are among the most important producers of fossil fuels, and they are important components of sedimentary rocks.

learning outcomes

You should be able to:

- Describe the complex life cycle of a parasite that involves multiple hosts.
- Summarize the consequences of overproduction of some diatoms and dinoflagellates.
- Describe beneficial and harmful interactions among species that involve protists.
- Give examples of protists that are important to humans.

1. What is the role of female *Anopheles* mosquitoes in the transmission of malaria?
2. Explain the roles of dinoflagellates in the two very different phenomena of coral bleaching and red tides.
3. What are two ways in which diatoms are important to human society?

The next six chapters will explore the major evolutionary radiations of multicellular eukaryotes, along with the protist ancestors from which they arose. [Chapters 27](#) and [28](#) will describe the origin and diversification of plants, [Chapter 29](#) will present the fungi, and [Chapters 30-32](#) will provide a brief overview of the animals.

Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching?

experiment

Original Paper: Lewis, C. L. and M. A. Coffroth. 2004. The acquisition of exogenous algal symbionts by an octocoral after bleaching. *Science* 304: 1490–1492.

Some corals lose their chief nutritional source when their photosynthetic endosymbionts die, often as a result of changing environmental conditions. This experiment by Cynthia Lewis and Mary Alice Coffroth investigated the ability of corals to acquire new endosymbionts after bleaching.

HYPOTHESIS▶ Bleached corals can acquire new photosynthetic endosymbionts from their environment.

METHOD

1. Count numbers of *Symbiodinium*, a photosynthetic dinoflagellate, living symbiotically in samples of a coral (*Briareum* sp.).
2. Stimulate bleaching by maintaining all *Briareum* colonies in darkness for 12 weeks.
3. After 12 weeks of darkness, count numbers of *Symbiodinium* in the coral samples; then return all colonies to light.
4. In some of the bleached colonies (the experimental group), introduce *Symbiodinium* strain B211—dinoflagellates that contain a unique molecular marker. Do not expose the others (the control group) to strain B211. Maintain both groups in the light for 6 weeks.

RESULTS

Pre-bleach

Post-bleach

CONCLUSION▶ Corals can acquire new endosymbionts from their environment following bleaching.

work with the data

The data in the table below come from DNA analyses of *Symbiodinium* strains found in the experimental and control colonies of corals (*Briareum*) before and after bleaching. *Symbiodinium* strain B211 (which was not present before bleaching) was introduced to the experimental colonies after bleaching. Use these data to answer the questions below.

	<i>Symbiodinium</i> strain present (% of colonies)			
	Non-B211	B211	None ^a	Colony died
Experimental colonies (strain B211 added)				
Pre-bleach	100	0	0	0
Post-bleach	58	0	42	0
Week 3	0	92	0	8
Week 6	8	58	8	25
Control colonies (no strain B211)				
Pre-bleach	100	0	0	0
Post-bleach	67	0	33	0
Week 3	67	0	33	0
Week 6	67	0	17	17

^aColonies remained alive but no *Symbiodinium* were detected.

QUESTIONS

1. Are new strains of *Symbiodinium* taken up only by coral colonies that have lost all their original endosymbionts?
2. Does the acquisition of a new *Symbiodinium* strain always result in survival of a recovering *Briareum* colony?
3. In week 3, only strain B211 was detected in the experimental colonies, but in week 6, non-B211 *Symbiodinium* were detected in 8 percent of the experimental colonies. Can you suggest an explanation for this observation?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

investigatinglife

Red tides are harmful, but how are dinoflagellates beneficial to marine ecosystems?

The opening of this chapter discussed harmful red tides, or blooms of dinoflagellates. But not all dinoflagellate blooms produce problems for other species. Dinoflagellates are important components of many ecosystems, as we have seen throughout this chapter. photosynthetic dinoflagellates also produce much of the atmospheric oxygen that most animals need to survive.

As we saw in Investigating Life: Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching?, corals and many other species depend on symbiotic dinoflagellates for food. In addition, as photosynthetic organisms, free-living planktonic dinoflagellates are among the most important primary producers in aquatic food webs. They are a major component of the phytoplankton and provide an important food source for many species (see [key Concept 26.4](#)).

Future directions

Some dinoflagellates produce a beautiful bioluminescence ([Figure 26.21](#)). Unlike the bioluminescent bacteria described at the start of [Chapter 26](#), however, dinoflagellates cannot generate a steady bioluminescence, but produce bright flashes of light when disturbed, as people who swim in the ocean at night in certain regions often observe. What function do these flashes serve? Many light-emitting dinoflagellates are preyed on by other species, such as small crustaceans. When the dinoflagellates produce a bright flash, it functions like a “burglar alarm,” and attracts secondary predators of the crustaceans. Experiments have shown that crustaceans reduce their feeding on dinoflagellates when they flash this signal. However, recent research shows another function of bioluminescence in toxic species of dinoflagellates. These toxic species produce a much lower intensity bioluminescence which may function as a warning of their toxicity to potential predators. So depending on the intensity and other details of the flash in different species, the bioluminescence can serve either to attract secondary predators or to warn off primary predators. Research on communication by bioluminescence continues as a rich field of investigation.

Figure 26.21 Light Up the Sea Bioluminescent dinoflagellates flash as an outrigger disturbs the ocean surface off the island of Bali.

Media Clip 26.8 Flashing Dinoflagellates www.Life11e.com/mc26.8

► 26.1 Eukaryotes Acquired Features from Both Archaea and Bacteria

- The term **protist** does not describe a formal taxonomic group. It is shorthand for “all eukaryotes that are not plants, animals, or fungi.”
- Early events in the evolution of the eukaryotic cell included the loss of the firm cell wall and infolding of the cell membrane. Such infolding led to segregation of the genetic material in a membrane-enclosed nucleus. **Review Focus: Key Figure 26.1**
- Mitochondria evolved by endosymbiosis with a proteobacterium.
- **Primary endosymbiosis** of a eukaryote and a cyanobacterium gave rise to the first chloroplasts. **Secondary endosymbiosis** and tertiary endosymbiosis between chloroplast-containing eukaryotes and other eukaryotes gave rise to the distinctive chloroplasts of euglenids, dinoflagellates, and other groups. **Review Figure 26.2, Animation 26.1**

primary endosymbiosis The engulfment of a cyanobacterium by a larger eukaryotic cell that gave rise to the first photosynthetic eukaryotes with chloroplasts.

secondary endosymbiosis The engulfment of a photosynthetic eukaryote by another eukaryotic cell that gave rise to certain groups of photosynthetic eukaryotes (e.g., euglenids).

► 26.2 Major Lineages of Eukaryotes Diversified in the Precambrian

- Most eukaryotes can be placed in one of eight major clades that diverged about 1.5 billion years ago: alveolates, stramenopiles, rhizarians, excavates, plants, amoebozoans, fungi, and animals. **Review Figure 26.3**
- Most, but not all, protists are unicellular.
- **Alveolates** are unicellular organisms with sacs (alveoli) beneath their cell membranes. Alveolate clades include the marine dinoflagellates, the parasitic apicomplexans, and the diverse, highly motile ciliates. **Review Activity 26.1, Animation 26.2**
- Stramenopiles typically have two flagella of unequal length, the longer one bearing rows of tubular hairs. Among the stramenopiles are the unicellular diatoms; the multicellular brown algae; and the nonphotosynthetic oomycetes, many of which are saprobic.
- Rhizarians are unicellular and aquatic. They include the cercozoans; the foraminiferans, which secrete shells of calcium carbonate; and the radiolarians, which have thin, stiff pseudopods and glassy endoskeletons.
- The excavates include parasitic as well as free-living species. The diplomonads and parabasalids lack typical mitochondria. Heteroloboseans have an amoeboid body form and a two-stage life cycle. Euglenids have anterior flagella; some are photosynthetic. The kinetoplastids, which include several human pathogens, have a single, large mitochondrion.
- The **amoebozoans** move by means of **lobe-shaped** pseudopods. A lobosean consists of a single amoeboid cell. **Plasmodial slime** molds are amoebozoans whose vegetative

stage is a **coenocyte** that moves by cytoplasmic streaming. In **cellular slime molds**, the individual cells maintain their identity at all times but aggregate to form fruiting structures.

► 26.3 Protists Reproduce Sexually and Asexually

- Asexual reproduction gives rise to clonal lineages of organisms.
- Conjugation in *Paramecium* is a sexual process but not a reproductive one. **Review Figure 26.19**
- Alternation of generations, which includes a multicellular diploid stage and a multicellular haploid stage, is a feature of many multicellular protist life cycles (as well as those of some fungi and all land plants). The alternating generations may be **heteromorphic** or **isomorphic**.

heteromorphic (het' er oh more' fik) [Gk. different form] Having a different form or appearance, as two heteromorphic life stages of a plant. (Contrast with isomorphic.)

isomorphic (eye so more' fik) [Gk. *isos*: equal + *morphe*: form] Having the same form or appearance, as when the haploid and diploid life stages of an organism appear identical. (Contrast with heteromorphic.)

► 26.4 Protists Are Critical Components of Many Ecosystems

- The diatoms are responsible for about one-fifth of the photosynthetic carbon fixation on Earth. They and other members of the phytoplankton are important primary producers in the marine environment. Ancient diatoms are a major source of today's petroleum and natural gas deposits.
- Some protists are pathogens of humans and other vertebrates. **Review Figure 26.20, Animation 26.3**
- Endosymbiotic relationships are common among microbial pro-tists and often benefit both the endosymbionts and their protist or animal partners. **Review Investigating Life: Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching?**

Review

6.2 Ciliates are named for their numerous hair-like cilia.

6.2 Apicomplexans possess an apical complex.

Because closely related organisms are more likely to share characteristics than are more distantly related ones, biologists can use phylogenetic information to make predictions about organisms based on what is known about their relatives. This exercise examines such use of phylogenies in the alveolates. Below is a phylogenetic tree for some of the alveolates, along with a table listing some of the characteristics for selected species.

Species	Features
<i>Theileria parva</i>	Parasite of cattle, transmitted by ticks
<i>Perkinsus marinus</i>	Parasite of oysters; marine habitat
<i>Cryptothecodinium cohnii</i>	Used to manufacture omega-3 fatty acids
<i>Oxyrrhis marina</i>	Omnivorous grazer; produces red tides
<i>Pfiesteria shumwayae</i>	Can be predatory on fish; can use chloroplasts of ingested green algae for photosynthesis

Questions

1. Based on this information and what you learned in the text, what life-history attribute was likely present in the common ancestor of the apicomplexans but not in other alveolates? Be as specific as possible.
2. Suppose a researcher examining the apicomplexans was considering which dinoflagellates to sample as an outgroup. Based on the phylogeny, is there a reason to favor choosing one particular genus of dinoflagellates over the others? If so, which genus? Explain your answer.
3. Suppose a researcher was studying the feeding mode of the genus *Pfiesteria* and wanted to determine if particular features evolved within this genus or were present in the ancestor of *Pfiesteria*. Based on the phylogeny, is there a reason to target sampling to a particular genus of dinoflagellate (outside *Pfiesteria*) over the others? If so, which genus? Explain your answer.
4. The red tides produced by *Oxyrrhis* and other dinoflagellates are not produced by apicomplexans. Similar red tides are produced by diatoms, which are distantly related to alveolates. Thus the production of red tides is convergent in these two groups. Describe another example from the text of convergent evolution in protists but outside alveolates.

Plants without Seeds: From Water to Land

Mosses, Iycophytes, and ferns cover the trees and ground in this temperate rainforest.

key concepts

- [7.1 Primary Endosymbiosis Produced the First Photosynthetic Eukaryotes](#)
- [7.2 Key Adaptations Permitted Plants to Colonize Land](#)
- [7.3 Vascular Tissues Led to Rapid Diversification of Land Plants](#)

A Toxic Spill of Ancient Fossil Algae

In the Gulf of Mexico, about 60 kilometers south of the Louisiana coast, the oil rig *Deepwater Horizon* was drilling an exploratory oil well in the seafloor beneath about 1,500 meters of water when, on April 20, 2010, an explosive blowout occurred and could not be contained. Over the next 3 months, almost 5 million barrels of petroleum flowed from the well into the Gulf, making this event the worst marine oil spill in history. The spill caused massive mortality among marine life, as well as considerable damage along the coast as the oil floated to the surface and washed ashore.

Why was oil to be found so deep beneath the Gulf, and what led geologists to expect to find oil there? Most people know that petroleum is a fossil fuel, meaning that it is derived from the ancient remains of once-living organisms. Fewer people know that most petroleum is derived largely from the remains of phytoplankton, including many species of green algae (as well as other microbial groups, as discussed in [Chapter 26](#)). These algae produce complex hydrocarbons through photo-synthesis. They accumulate hydrocarbons both as an energy reserve and as a way to increase their buoyancy in water. When these algae die, they drop to the bottom of the ocean, and over many millions of years, their buried remains decompose into petroleum deposits.

Today there is great interest in using solar power to help meet human energy needs. But unicellular eukaryotes capitalized on this process first, and very long ago. Singlecelled eukaryotes incorporated tiny solar energy converters into their cells about 1.5 billion years ago, when they formed partnerships with photosynthetic cyanobacteria. These endosymbionts—which over time would become the chloroplasts of modern plants—allowed many eukaryotes to use solar energy to drive the reactions that convert carbon dioxide into organic carbon compounds. Over many millions of years, the carbon compounds produced in the cells of marine algae accumulated in ocean sediments. Today humans are tapping that trapped solar energy in the form of petroleum and other fossil fuels.

QA Given that petroleum is derived naturally from green algae, can humans use green algae to produce oil commercially?

27.1 Primary Endosymbiosis Produced the First Photosynthetic Eukaryotes

More than a billion years ago, when a cyanobacterium was first engulfed by an early eukaryote, the history of life was altered radically. The chloroplasts that resulted from primary endosymbiosis of this cyanobacterium (see [Figure 26.2](#)) were obviously important for the evolution of plants and other photosynthetic eukaryotes, but they were also critical to the evolution of all life on land. Until photosynthetic plants were able to move onto land, there was very little on land to support multicellular animals or fungi, and almost all life was restricted to the oceans and fresh waters.

focus your learning

The major clades of *Plantae* evolved from the first photosynthetic eukaryote.

Key evolutionary innovations evolved among the aquatic *Plantae*.

Land plants fall into ten major clades.

Primary endosymbiosis is a shared derived trait—a **synapomorphy**—of the group known as **Plantae** ([Figure 27.1](#)). Although *Plantae* is Latin for “plants,” in everyday language—and throughout this book—the unmodified common name “plants” is usually used to refer only to the land plants. However, the first several clades to branch off the tree of life after primary endosymbiosis are all aquatic. Most aquatic photosynthetic eukaryotes (other than those secondarily derived from land plants) are known by the common name **algae**. This name, however, is just a convenient way to refer to these groups, which are not all closely related. Many of the photosynthetic groups discussed in [Chapter 26](#) (which acquired chloroplasts through secondary endosymbiosis) are also commonly called algae.

Figure 27.1 The Evolution of Plants In its broadest definition, the term “plant” includes the glaucophytes, red algae, and green plants—all the groups descended from a common ancestor that had chloroplasts (A). Some biologists restrict the term “plant” to the green plants (those with chlorophyll *b*) or, even more narrowly, to the land plants (B). Three key characteristics that emerged during the evolution of land plants—protected embryos, vascular tissues, and seeds—led to their success in the terrestrial environment.

Q: Which two names of plant groups are used in this figure only as convenience terms, and

do not refer to clades?

work with the data

The Phylogeny of Land Plants

Original Paper: Qiu, Y.-L. et al. 2006. The deepest divergences in land plants inferred from phylogenetic evidence. *Proceedings of the National Academy of Sciences USA* 103: 15511–15516.

In addition to the morphological characters of land plants shown on the phylogeny in Figure 27.1, DNA sequences are widely used to study and reconstruct the evolutionary history of plants. These sequences are many tens of thousands of nucleotides long and have been collected from a large number of species. The full data set used by Yin-Long Qiu and his colleagues (available at treebase.org) includes DNA sequences from 67 genes. The table below provides sample sequences from a chloroplast gene that has been used to reconstruct the relationships of representative plant species; the table shows 27 nucleotide positions for 10 species.

QUESTIONS

1. Construct a phylogenetic tree of these 10 species using the parsimony method (see Key Concept 21.2 and the examples in Table 21.1 and Figure 21.5 for instructions). Use the outgroup to root your tree. Assume that all changes among nucleotides are equally likely.
2. How many changes (from one nucleotide to another) occur along each branch on your tree?
3. Which nucleotide positions (i.e., which character states) exhibit homoplasy (convergence or reversal of the character state)?
4. Which group on your tree represents the streptophytes? The land plants? The vascular plants? The euphyllophytes?

	Nucleotide position (character state)

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Several distinct clades of algae were among the first photosynthetic eukaryotes

The ancestor of Plantae was unicellular and may have been similar in general form to the modern **glaucophytes** (Figure 27.2). These microscopic freshwater algae are thought to be the sister group of the rest of Plantae (see Figure 27.1A). The chloroplast of glaucophytes is unique in containing a small amount of peptidoglycan between its inner and outer membranes—the same arrangement found in cyanobacteria. Peptidoglycan has been lost from the remaining photosynthetic eukaryotes.

Figure 27.2 Glaucophytes May Resemble Some of the Earliest Plantae The large chloroplasts of unicellular glaucophytes differ from chloroplasts of other Plantae in

retaining a layer of peptidoglycan. This feature is thought to have been retained from the endosymbiotic cyanobacteria that gave rise to the chloroplasts of *Plantae*. The photograph shows a colony of two individuals, each with two chloroplasts.

In contrast to the glaucophytes, almost all **red algae** are multicellular ([Figure 27.3](#)). Their characteristic color is a result of the accessory photosynthetic pigment [phycoerythrin](#), which is found in relatively large amounts in the chloroplasts of many red algae. In addition to phycoerythrin, red algal chloroplasts contain chlorophyll *a* as well as several other accessory pigments.

(A) *Rhodymenia* sp.

1 cm

(B) *Calliarthron* sp.

3 mm

Figure 27.3 Red Algae Contain a Red Accessory Photosynthetic Pigment (A) The rich red color of red algae is a result of the pigment phycoerythrin. (B) Coralline red algae is named for its coral-like appearance.

phycoerythrin A red protein pigment that occurs in red algae.

The red algae include species that grow in the shallowest tide pools as well as the photosynthesizers found deepest in the ocean (as deep as 260 m if nutrient conditions are right and the water is clear enough to permit light to penetrate). A few red algae inhabit fresh water. Most grow attached to a substrate by a holdfast.

Despite their name, red algae don't always appear red in color. The ratio of two pigments—phycoerythrin (red) and chlorophyll *a* (green)—depends largely on the intensity of light that reaches the alga. In deep water, where light is dim, algae accumulate large amounts of phycoerythrin and appear red. But many species growing near the surface contain a higher concentration of chlorophyll *a* and thus appear bright green.

The remaining algal groups in Plantae are the various “green algae.” Like land plants, the green algae contain both chlorophylls *a* and *b* and store their reserve of photosynthetic products as starch in chloroplasts. All the groups that share these features are commonly called **green plants** because both of their photosynthetic pigments are green.

The largest clade of “green algae” is the **chlorophytes**. There are more than 17,000 species of chlorophytes, most of which are aquatic (some are marine, though more are freshwater forms), although there are a few terrestrial forms that live in moist environments. Chlorophytes range in size from microscopic unicellular forms to multicellular forms many centimeters long and display an incredible variety of shapes and body forms. Surprisingly large and well-formed colonies of cells are found in some unicellular freshwater groups, such as the genus *Volvox* ([Figure 27.4A](#)). Certain cells in these colonies are specialized for reproduction. The cells in these colonies are not differentiated into specialized tissues and organs, as in land plants and animals, but they show vividly how the preliminary step of this great evolutionary innovation might have been taken.

(A) *Volvox* sp.

(B) *Ulva latuca*

Figure 27.4 Chlorophytes Display a Wide Diversity of Forms (A) *Volvox* colonies are precisely spaced arrangements of individual cells. Specialized reproductive cells produce daughter colonies, which will eventually release new individuals. **(B)** Sea lettuce grows in marine waters and intertidal areas.

Volvox is a colonial unicellular chlorophyte, but there are also many true multicellular species of chlorophytes. Some of these are filamentous. Others, like species in the genus *Ulva* ([Figure 27.4B](#)), grow into thin, membranous sheets up to 30 centimeters in width.

▶ investigatinglife Can *Chlorella* Algae Be Grown in Municipal Sewage Wastewater for Biofuel Production?

experiment

Original Paper: Bhatnagar, A., M. Bhatnagar, S. Chinnasamy and K. C. Das. 2010. *Chlorella minutissima*—A promising fuel alga for cultivation in municipal wastewaters. *Applied Biochemistry and Biotechnology* 161: 523–536.

Growing algae for use in biofuel production requires an abundant source of freshwater that contains appropriate nutrients. Appropriate nutrients for growing algae are present in municipal wastewater, but other contaminants of wastewater (such as salts and detergents) could diminish algal growth. Ashish Bhatnagar and his colleagues at the University of Georgia conducted an experiment to see if *Chlorella minutissima* algae could be grown successfully in municipal wastewater.

HYPOTHESIS▶ *Chlorella minutissima* algae can be grown successfully in municipal wastewater, either with or without dilution from traditional growth medium.

METHOD

1. Grow replicate cultures of a standard inoculate of *Chlorella minutissima* algae in growth medium, as well as in 25%, 50%, 75%, and 100% municipal wastewater.
2. Control temperature and light conditions for all cultures.
3. Measure growth of the algae after 15 days by measuring the concentration of chlorophyll *a* present in each culture.

RESULTS

CONCLUSIONS▶ *Chlorella minutissima* algae can be grown effectively in municipal wastewater, and growth may even exceed production in standard growth medium.

Q: At what tested concentration of wastewater does the algae grow the best?

work with the data

After determining that municipal wastewater could be used to grow *Chlorella minutissima* for biofuel production, Ashish Bhatnagar and his colleagues explored the effects on *Chlorella* growth of various sources of carbon that were present in the wastewater. The table below shows three measures of algal growth in standard growth medium, as well as in the medium with added sources of carbon. Use these data to answer the following questions.

QUESTIONS

1. Calculate 95% confidence intervals for mean measures of chlorophyll *a* concentration in the various growth media (see Appendix B for

directions on calculating confidence intervals from standard errors). Which carbon source additives result in significantly higher or lower chlorophyll *a* concentrations (based on non-overlapping confidence intervals) compared with the growth medium only?

2. Plot the measures for chlorophyll *a* concentration, biomass, and cell count for each growth condition. Which two measures appear to be most strongly correlated? Can you think of reasons why the uncorrelated measure might show a different trend than the two correlated measures?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Measurement ^a	Growth medium only	Growth medium + propionate	Growth medium + acetate	Growth medium + citrate	Growth medium + sucrose	Growth medium + glucose
Chlorophyll <i>a</i> concentration (mg/L)	13.41 (1.24)	1.72 (0.03)	9.4 (0.82)	15.26 (0.59)	17.63 (0.86)	37.21 (3.76)
Biomass (mg/L)	899 (27.6)	120 (12.6)	630 (35.1)	1,007 (110.4)	1,164 (87.9)	2,456 (297.7)
Cell count (per 10 ⁻⁵ mL)	2.01 (0.17)	0.51 (0.02)	1.89 (0.08)	1.50 (0.07)	1.93 (0.17)	1.76 (0.18)

^a Measures are means, with standard errors of mean shown in parentheses.

Biologists are exploring mass production of several species of chlorophytes as a source of biofuels. One of the biggest limitations in using algae for biofuels relates to the cost of providing an appropriate growth medium for the algae. Growth media typically require fresh water and abundant sources of carbon, nitrogen, and phosphorus. These nutrients are already present in most municipal wastewater supplies, and the removal of these nutrients by growing algae would help clean the water supply. **Investigating Life: Can *Chlorella* Algae Be Grown in Municipal Sewage Wastewater for Biofuel Production?** explores the potential of municipal wastewater as a growth medium for algae used in biofuel production.

Two groups of green algae are the closest relatives of land plants

All green algae other than the chlorophytes form a group together with the land plants known as **streptophytes** (see **Figure 27.1A**). Several microscopic structural features, backed by clear evidence from molecular studies, indicate that the closest relatives of the land plants are two groups of aquatic green algae, the **coleochaetophytes** (**Figure 27.5A**) and the **stoneworts**

([Figure 27.5B](#)). Both of these multicellular algal groups retain their eggs in the parental organism, as land plants do. As in land plants, the cytoplasm of adjacent cells in these algal groups is connected through structures called plasmodesmata; they also share similarities in the details of mitosis and cytokinesis. Of these two groups, stoneworts are thought to be the sister group of land plants (see [Figure 27.1A](#)). The growth form of stoneworts is branching and apical (new growth occurs at the tips of branches), as in most land plants. Phylogenetic analysis of gene sequences has confirmed the close relationships of coleochaetophytes and stoneworts to the land plants.

150 μm

(B) *Chara rusbyana* (stonewort)

Figure 27.5 The Closest Relatives of Land Plants (A) This species is a representative of the co-leochaetophytes, the sister clade of stoneworts plus land plants. (B) The land plants probably evolved from a common ancestor shared with the stoneworts, an abundant group of multicellular green algae often found in freshwater pools and lakes (although a few species are found in marine environments). A species in the common genus *Chara* is shown here.

 Media clip 27.1 **Reproductive Structures of Stoneworts** www.Life11e.com/mc27.1

There are ten major groups of land plants

One of the key synapomorphies of the **land plants** is development from an embryo that is protected by tissues of the parent plant. For this reason, land plants are sometimes called **embryophytes** (*phyton*, “plant”). The green plants, the streptophytes, and the land plants have each been called “the plant kingdom” by different authorities; others take an even broader view and include red algae and glaucophytes as “plants.” To avoid confusion in this chapter, we will use modifying terms (e.g., “land plants” or “green plants”) to refer to the various clades of Plantae shown in [Figure 27.1](#).

The land plants that exist today fall naturally into ten major clades (listed by their common names in the center column of [Table 27.1](#)). Members of seven of those clades possess well-developed vascular systems that transport materials throughout the plant body. We call these seven groups, collectively, the **vascular plants**, or **tracheophytes**, because they all possess fluid-conducting cells called [tracheids](#) (discussed in more detail in [Chapter 34](#)). The remaining

three clades (liverworts, mosses, and hornworts) lack tracheids and are referred to collectively as nonvascular land plants. Note, however, that the three groups of **nonvascular land plants** do *not* form a clade (unlike the vascular plants, which *are* a clade).

table 27.1 Classification of Land Plants		
Group	Common name	Characteristics
NONVASCULAR LAND PLANTS		
Hepatophyta	Liverworts	No stomata; gametophyte flat or leafy
Bryophyta	Mosses	Filamentous stage; gametophyte leafy; sporophyte grows apically (at the tip)
Anthocerotophyta	Hornworts	Embedded archegonia; sporophyte grows basally (i.e., from the ground)
VASCULAR PLANTS		
Lycopodiophyta	Lycophytes: Club mosses and allies	Microphylls in spirals; sporangia in leaf axils
Monilophyta	Horsetails, ferns	Simple leaves in whorls or frondlike compound leaves
Seed plants		
Gymnosperms		
Cycadophyta	Cycads	Compound leaves; swimming sperm; seeds on modified leaves
Ginkgophyta	Ginkgo	Deciduous; fan-shaped leaves; swimming sperm
Gnetophyta	Gnetophytes	Vessels in vascular tissue; opposite, simple leaves
Coniferophyta	Conifers	Seeds in cones; needle- or scalelike leaves
Angiosperms	Flowering plants	Endosperm; carpels; gametophytes much reduced; seeds contained within fruits

tracheid (tray' kee id) A type of tracheary element found in the xylem of nearly all vascular plants, characterized by tapering ends and walls that are pitted but not perforated. (Contrast with vessel element.)

nonvascular land plants All land plants that lack a vascular system.

27.1 recap

Primary endosymbiosis is a synapomorphy of the Plantae. The glaucophytes, the sister clade of the other Plantae, are unicellular algae that are similar to some of the earliest photosynthetic eukaryotes. The green plants contain chlorophyll *b* in addition to the chlorophyll *a* found in all Plantae.

learning outcomes

You should be able to:

- Plot the origin and distribution of key evolutionary innovations among aquatic Plantae.
- Describe the major clades of Plantae and their relationships to one another.

1. Explain the different possible uses of the term “plant.”
2. Why doesn’t the term “algae” designate a formal taxonomic group?

3. What are some of the key differences between glaucophytes, red algae, and the various clades of green algae?
4. What evidence supports the phylogenetic relationship between land plants and the various groups of aquatic green algae?

The green algal ancestors of the land plants lived at the margins of ponds or marshes, ringing them with a mat of dense green. It was from such a marginal habitat, which was sometimes wet and sometimes dry, that early plants made the transition onto land.

***connect the concepts** As noted in [Key Concept 21.1](#), derived traits shared by a group of organisms that offer evidence of their common ancestry are called synapomorphies.

27.2 Key Adaptations Permitted Plants to Colonize Land

How did the land plants arise? To address this question, we can compare land plants with their closest relatives among the green algae. The features that differ between the two groups include the adaptations that allowed the first land plants to survive in the terrestrial environment.

focus your learning

Key innovations of Plantae facilitated their transition to land.

Alternation of generations is a universal trait of the Plantae.

Adaptations to life on land distinguish land plants from green algae

Land plants first appeared in the terrestrial environment between 450 and 500 million years ago. How did they survive in an environment that differed so dramatically from the aquatic environment of their ancestors? While the water essential for life is everywhere in the aquatic environment, water is difficult to obtain and retain in the terrestrial environment.

No longer bathed in fluid, organisms on land faced potentially lethal desiccation (drying). Large terrestrial organisms had to develop ways to transport water to body parts distant from the source of the water. And whereas water provides aquatic organisms with support against gravity, a plant living on land must either have some other support system or sprawl unsupported on the ground. A land plant must also use different mechanisms for dispersing its gametes and progeny than its aquatic relatives, which can simply release them into the water.

Survival on land was facilitated by the evolution among plants of numerous adaptations, including:

The *cuticle*, a membrane covered in waxes to retard water loss

Stomata, small openings in leaves and stems that open and close to regulate gas exchange and water loss

Gametangia, multicellular organs that enclose plant gametes and prevent them from drying out

Embryos, young plants contained within a protective structure

Certain *pigments* that afford protection against the mutagenic ultraviolet radiation that bathes the terrestrial environment

Thick *spore walls* containing a polymer that protects the spores from desiccation and resists decay

A *mutually beneficial association with fungi* (mycorrhizae) that promotes nutrient uptake from the soil

The cuticle may be the most important—and the earliest—of these features. Composed of several unique waxy lipids that coat the leaves and stems of land plants, the cuticle has several functions, the most obvious and important of which is to keep water from evaporating from the plant body.

As ancient plants colonized the land, they not only adapted to the terrestrial environment, they also modified it by contributing to the formation of soil. Acids secreted by plants helped break down rock, and the organic compounds produced by the breakdown of dead plants contributed

nutrients to the soil. Such effects are repeated today wherever plants colonize and grow in new areas.

Life cycles of land plants feature alternation of generations

A universal feature of the life cycles of land plants is alternation of generations. Recall from [Key Concept 26.3](#) the two hallmarks of alternation of generations:

- . The life cycle includes both a multicellular diploid stage and a multicellular haploid stage.
- . Gametes are produced by mitosis, not by meiosis. Meiosis produces [spores](#) that develop into multicellular haploid organisms.

spore [Gk. *spora*: seed] (1) Any asexual reproductive cell capable of developing into an adult organism without gametic fusion. In plants, haploid spores develop into gametophytes, diploid spores into sporophytes. (2) In prokaryotes, a resistant cell capable of surviving unfavorable periods.

If we begin looking at the land plant life cycle at the single-cell stage—the diploid zygote—then the first phase of the cycle is the formation, by mitosis and cytokinesis, of a multicellular [embryo](#), which eventually grows into a mature diploid plant. This multicellular diploid plant is called the [sporophyte](#) (“spore plant”).

embryo [Gk. *en*: within + *bryein*: to grow] A young animal, or young plant sporophyte, while it is still contained within a protective structure such as an egg, uterus, or seed.

sporophyte (spor’ o fyte) [Gk. *spora*: seed + *phyton*: plant] In plants and protists with alternation of generations, the diploid phase that produces the spores. (Contrast with gametophyte.)

Cells contained within specialized reproductive organs of the sporophyte, called **sporangia** (singular *sporangium*), undergo meiosis to produce haploid, unicellular spores. By mitosis and cytokinesis, a spore develops into a haploid plant. This multicellular haploid plant, called the [gametophyte](#) (“gamete plant”), produces haploid gametes by mitosis. The fusion of two gametes (fertilization) forms a single diploid cell—the zygote—and the cycle is repeated ([Figure 27.6](#)).

gametophyte (ga meet’ oh fyte) In plants and photosynthetic protists with alternation of generations, the multicellular haploid phase that produces the gametes. (Contrast with sporophyte.)

Figure 27.6 Alternation of Generations in Land Plants A multicellular diploid sporophyte generation that produces spores by meiosis alternates with a multicellular haploid gametophyte generation that produces gametes by mitosis.

Q: What is a major difference in the haploid portion of the life cycle of plants and animals?

The sporophyte generation extends from the zygote through the adult multicellular diploid plant and sporangium formation. In contrast, the gametophyte generation extends from the spore through the adult multicellular haploid plant to the gametes. The transitions between the generations are accomplished by fertilization and by meiosis. In all land plants, the sporophyte and the gametophyte differ genetically: the sporophyte has diploid cells, and the gametophyte has haploid cells.

There is a trend toward reduction of the gametophyte generation in plant evolution. In the nonvascular land plants, the gametophyte is larger, longer-lived, and more self-sufficient than the sporophyte. In those groups that appeared later in plant evolution, however, the sporophyte is the larger, more conspicuous, longer-lived, and more self-sufficient generation.

Nonvascular land plants live where water is readily available

The living species of nonvascular land plants are the liverworts, mosses, and hornworts. These three groups are thought to be similar in many ways to the earliest land plants. Most of these plants grow in dense mats, usually in moist habitats. Even the largest of these species are only about half a meter tall, and most are only a few centimeters tall or long. Why have they not evolved to be taller?

The probable answer is that they lack an efficient vascular system for transporting water and minerals from the soil to distant parts of the plant body.

The nonvascular land plants lack the true leaves, stems, and roots that characterize the vascular plants, although they have structures analogous to each. Their growth form allows water to move through the mats of plants by capillary action. They have leaflike structures that readily catch and hold any water that splashes onto them. They are small enough that minerals can be distributed throughout their bodies by diffusion. As in most land plants, layers of maternal tissue protect their embryos from desiccation. Nonvascular land plants also have a cuticle, although it is often very thin (or even absent in some species) and thus is not highly effective in retarding water loss.

Most nonvascular land plants live on the soil or on vascular plants, but some grow on bare rock, on dead and fallen tree trunks, and even on buildings. Their ability to grow on such marginal surfaces results from a ***mutualistic association with fungi**. The earliest association

of land plants with fungi dates back at least 460 million years. This mutualism probably facilitated the absorption of water and minerals, especially phosphorus, from the first soils.

Nonvascular land plants are widely distributed over six continents and even exist (albeit very locally) on the coast of the seventh, Antarctica. Most are terrestrial. Although a few species live in fresh water, these aquatic species are descended from terrestrial ones. None live in the oceans.

The sporophytes of nonvascular land plants are dependent on the gametophytes

In the nonvascular land plants, the conspicuous green structure visible to the naked eye is the gametophyte. The gametophyte is photosynthetic and is therefore nutritionally independent; the sporophyte may or may not be photosynthetic, but it is always nutritionally dependent on the gametophyte and remains permanently attached to it.

[Figure 27.7](#) illustrates the life cycle of a moss, which is typical of the life cycles of nonvascular land plants. A sporophyte produces unicellular haploid spores as products of meiosis within a sporangium. When a spore germinates, it gives rise to a multicellular haploid gametophyte whose cells contain chloroplasts and are thus photosynthetic. Eventually gametes form within specialized sex organs, called the **gametangia**. The [archegonium](#) is a multicellular, flaskshaped female sex organ with a long neck and a swollen base; each one produces a single egg. The [antheridium](#) is a male sex organ in which sperm, each bearing two flagella, are produced in large numbers. Archegonia and antheridia are produced on the same individual in many species, so each individual has both male and female reproductive structures. Adjacent individuals often fertilize one another's gametes, however, which helps maintain genetic diversity in the population.

Figure 27.7 A Life Cycle Dependent on Water The life cycles of nonvascular land plants, exemplified here by that of a moss, are dependent on an external source of liquid water. The visible green structure of such plants is the gametophyte, which contains haploid archegonia and antheridia. Water carries sperm from the antheridia into an archegonium, inside which an egg is fertilized and grows into a multicellular, diploid sporangium.

Animation 27.1 Life Cycle of a Moss www.Life11e.com/a27.1

Media clip 27.2 Nonvascular Plant Reproduction www.Life11e.com/mc27.2

archegonium (ar' ke go' nee um) The multicellular structure that produces eggs in nonvascular land plants, ferns, and gymnosperms.

antheridium (an' thur id' ee um) [Gk. *antheros*: blooming] The multicellular structure that produces the sperm in nonvascular land plants and ferns.

Once released from the antheridium, the sperm must swim or be splashed by raindrops to a nearby archegonium on the same or a neighboring plant—a constraint that reflects the aquatic

origins of the nonvascular land plants' ancestors. The sperm are aided on their journey by chemical attractants released by the egg or the archegonium. Before sperm can enter the archegonium, however, certain cells in the neck of the archegonium must break down, leaving a water-filled canal through which the sperm can swim to complete their journey. Notice that *all of these events require liquid water*.

Once sperm arrive at an egg, the nucleus of a sperm fuses with the egg nucleus to form a diploid zygote. Mitotic divisions of the zygote produce a multicellular, diploid sporophyte embryo. After the sporophyte grows out of the archegonium it produces a single sporangium, within which meiotic divisions produce spores and thus the next gametophyte generation.

Liverworts are the sister clade of the remaining land plants

There are about 9,000 species of [liverworts](#). Most liverworts have leafy gametophytes ([Figure 27.8A](#)). Some have thalloid gametophytes: green, leaflike layers that lie flat on the ground ([Figure 27.8B](#) and [C](#)). The simplest liverwort gametophytes are flat plates of cells, a centimeter or so long, that produce antheridia or archegonia on their upper surfaces and rhizoids (rootlike filaments) on their lower surfaces.

liver A large digestive gland. In vertebrates, it secretes bile and is involved in the formation of blood.

(A) *Lophocolea bidentata*

0.4 cm

Figure 27.8 Liverwort Diversity (A) The gametophyte of a leafy liverwort. (B) The gametophytes of the thalloid liverwort *Marchantia* lie flat on the ground. (C) *Marchantia* gametophytes bearing archegonia.

Liverwort sporophytes are shorter than those of mosses and hornworts, rarely exceeding a few millimeters. The liverwort sporophyte has a stalk that raises the sporangium above the gametophyte. In most species, the stalk elongates by expansion of cells throughout its length. This elongation raises the sporangium above ground level, allowing the spores to be dispersed more widely. The sporangia of liverworts are simple: a globular sporangium wall surrounds a mass of spores. In some species of liverworts, spores are not released by the sporophyte until the surrounding sporangium wall rots. In other liverworts, however, the spores are thrown from the sporangium by structures that shorten and compress as they dry out. When the stress becomes sufficient, the compressed structure snaps back to its resting position, throwing spores in all directions.

Among the most familiar thalloid liverworts are species of the genus *Marchantia*. *Marchantia* is easily recognized by the characteristic structures on which its male and female gametophytes bear their antheridia and archegonia (see [Figure 27.8C](#)). Like most liverworts, *Marchantia* also reproduces asexually by simple fragmentation of the gametophyte. In addition, *Marchantia* and some other liverworts and mosses reproduce asexually by means of gemmae (singular gemma), which are lens-shaped clumps of cells (see [Figure 27.8B](#)). In a few liverworts, the gemmae are held in structures called gemmae cups, which promote dispersal of the gemmae by raindrops.

 Media Clip 27.3 Liverwort Life Cycle www.Life11e.com/mc27.3

Water and sugar transport mechanisms emerged in the mosses

The most familiar of the nonvascular land plants are the **mosses**. These hardy little plants, of which there are about 15,000 species, are found in almost every terrestrial environment. They are often found on damp, cool ground, where they form thick mats ([Figure 27.9](#)). The mosses are the sister clade of the vascular plants plus the hornworts (see [Figure 27.1B](#)).

Figure 27.9 Mosses Often Cover the Ground in Dense Mats (A) Dense layers of moss carpet a field of solidified volcanic lava in Iceland. (B) A close-up view of moss.

The mosses, along with the hornworts and vascular plants, share an advance over the liverworts in their adaptation to life on land: they have openings called **stomata**, which allow CO_2 to enter the plant body and allow water and O_2 to leave it. Stomata are a syn-apomorphy of mosses and all other land plants except liverworts.

stoma (plural: stomata) [Gk. *stoma*: mouth, opening] Small opening in the plant epidermis that permits gas exchange; bounded by a pair of guard cells whose osmotic status regulates the size of the opening.

In mosses, the gametophyte begins its development following spore germination as a branched, filamentous structure called a pro-tonema (see [Figure 27.7](#)). Although the protonema looks a bit like a filamentous green alga, this structure is unique to the mosses. Some of the filaments contain chloroplasts and are photosynthetic; others, called rhizoids, are nonphotosynthetic and anchor the protonema to the substrate. After a period of linear growth, cells close to the tips of the photosynthetic filaments divide rapidly in three dimensions to form buds. The buds eventually develop a distinct tip, or apex, and produce the familiar leafy moss shoot with leaflike structures arranged spirally. These leafy shoots produce antheridia or archegonia (see [Figure 27.7](#)).

Some moss gametophytes are too large to transport enough water through their bodies solely by diffusion. Gametophytes and sporophytes of many mosses contain a type of cell called a hydroid, which dies and leaves a tiny channel through which water can travel. The hydroid is functionally similar to the tracheid, the characteristic water-conducting cell of the vascular plants, but it lacks lignin and the cell wall structure found in tracheids. The possession of hydroids and of a limited system for transport of sugar in some mosses shows that the term “nonvascular plant” is somewhat misleading when applied to these plants. Despite their simple system of internal transport, however, the mosses are not considered vascular plants because they lack tracheids or other components of xylem and phloem.

Mosses of the genus *Sphagnum* ([Figure 27.10A](#)) often grow in cool, swampy places, where the plants begin to decompose in water after they die. Rapidly growing upper layers of moss compress the deeper-lying, decomposing layers. Partially decomposed plant matter is called **peat**. In some parts of the world, people derive the majority of their fuel from peat bogs ([Figure 27.10B](#)). *Sphagnum*-dominated peat-lands cover a total area approximately half the size of the United States—more than 1 percent of Earth’s surface. Millions of years ago, continued compression of peat composed primarily of other seedless plants gave rise to coal.

(A)

Sphagnum sp.

(B)

Figure 27.10 *Sphagnum* Moss (A) *Sphagnum* bogs are extremely dense growths of the moss shown here in a close-up view. (B) Workers mine a bog for peat, a fossil fuel formed from decomposing *Sphagnum* mosses.

peat Partly decomposed vegetable matter, especially of sphagnum moss, that is typically formed in acidic bogs.

Hornworts have distinctive chloroplasts and stalkless sporophytes

The approximately 100 species of **hornworts** are so named because their sporophytes look like little horns ([Figure 27.11](#)). Hornworts appear at first glance to be liverworts with very simple gametophytes. Their gametophytes are flat plates of cells a few cells thick.

Anthoceros sp.

Figure 27.11 Hornworts Get Their Name from Their Hornlike Sporophytes Unlike liverworts and mosses, hornworts have sporophytes that are persistently green. The hornworts share this trait with the vascular plants.

Hornworts have several characteristics that distinguish them from liverworts and mosses. First, the cells of hornworts each contain a single large, platelike chloroplast, whereas the cells of the other two groups contain numerous small, lens-shaped chloroplasts. Second, of the sporophytes in all three groups, those of the hornworts come closest to being capable of growth without a set limit. Liverwort and moss sporophytes have a stalk that stops growing as the sporangium matures, so elongation of the sporophyte is strictly limited. The hornwort sporophyte, however, has no stalk, and it is persistently green (a trait shared with vascular plants). A basal region of the sporangium remains capable of indefinite cell division, continuously producing new spore-bearing tissue above. The sporophytes of some hornworts growing in mild and continuously moist conditions can become as tall as 20 centimeters. Eventually, however, the sporophyte's growth is limited by its simple transport system.

Hornworts have a symbiotic relationship with cyanobacteria that promotes their growth by providing them with access to nitrogen, which is often a limiting resource. Internal cavities of hornworts that are filled with mucilage can dry out, forming air-filled cavities through which cyanobacteria can enter. Cyanobacteria such as *Nostoc* convert atmospheric nitrogen gas into a form usable by their host plant; in return, the hornwort provides the symbiont with carbohydrates.

New features appeared in plants as they continued to adapt to the terrestrial environment. One of the most important of these was vascular tissues, the characteristic that defines the vascular plants.

27.2 recap

The transition of plants to land required numerous adaptations, including the cuticle, stomata, gametangia, protected embryos, pigments, thick spore walls, and mutually beneficial associations with fungi. Nonvascular land plants rely on liquid water for reproduction.

learning outcomes

You should be able to:

- Describe one or more key innovations in land plants that were most important for their transition to a terrestrial environment, and justify your choice(s).
- Distinguish alternation of generations as seen in plants from the life cycles of animals.

-
1. Explain what is meant by “alternation of generations” Why do we not use this phrase for humans?
 2. Describe key adaptations of plants to the terrestrial environment, and describe the distribution of those adaptations among the liverworts, mosses, and hornworts.

***connect the concepts** Land plants of many groups have mutualistic associations with fungi, as described in [Key Concept 29.2](#).

27.3 Vascular Tissues Led to Rapid Diversification of Land Plants

The first plants possessing vascular tissues did not arise until tens of millions of years after the earliest nonvascular plants had colonized the land. But once vascular tissues arose, their ability to transport water and food throughout the plant body allowed the vascular plants to spread to new terrestrial environments and to diversify rapidly.

focus your learning

Vascular tissues have several functions that allowed plants to colonize land.

The precursors of vascular plants are extinct.

Vascular plants evolved specialized structures and processes for transporting water, minerals, and the products of photosynthesis.

Horsetails and ferns are more closely related than previously thought.

Homospores produce a single type of spore, while heterospores produce two types: megaspores and microspores.

Vascular tissues transport water and dissolved materials

The key synapomorphy of the vascular plants is a well-developed vascular system containing two types of tissues that are specialized for the transport of materials from one part of the plant to another. One type of vascular tissue, the **xylem**, conducts water and minerals from the soil to aerial parts of the plant. Because some of its cell walls contain a stiffening substance called lignin, xylem also provides support against gravity in the terrestrial environment. The other type of vascular tissue, the **phloem**, conducts the products of photosynthesis from sites where they are produced or released to sites where they are used or stored. (We will discuss xylem and phloem in detail in [Chapters 33](#) and [34](#).)

xylem (zy' lum) [Gk. *xylon*: wood] In vascular plants, the tissue that conducts water and minerals; xylem consists, in various plants, of tracheids, vessel elements, fibers, and other highly specialized cells.

phloem (flo' um) [Gk. *phloos*: bark] In vascular plants, the vascular tissue that transports sugars and other solutes from sources to sinks.

Although the vascular plants are an extraordinarily large and diverse group, one particular event was critical to their evolution. Sometime during the Paleozoic era, probably in the mid-Silurian (430 mya), a new cell type—the tracheid—evolved in sporophytes of the earliest vascular plants. The tracheid is the principal water-conducting element of the xylem in all vascular plants except the angiosperms (flowering plants) and gnetophytes—and tracheids persist even in these groups, along with a more specialized and efficient system derived from them.

The evolution of tracheids set the stage for the complete and permanent invasion of land by plants. First, these cells provided a pathway for the transport of water and mineral nutrients from

a source of supply to regions of need in the plant body. Second, the cell walls of tracheids, stiffened by lignin, provided rigid structural support. This support is a crucial factor in a terrestrial environment because it allows plants to grow upward and thus compete for sunlight. A taller plant can intercept more direct sunlight (and thus conduct photosynthesis more readily) than a shorter plant, which may be shaded by the taller one. Increased height also improves the dispersal of spores.

The vascular plants featured another evolutionary novelty: a branching, independent sporophyte. A branching sporophyte body can produce more spores than an unbranched body, and it can develop in complex ways. The sporophyte of a vascular plant is nutritionally independent of the gametophyte at maturity. Among the vascular plants, the sporophyte is the large and obvious plant one normally notices in nature, in contrast to the relatively small, dependent sporophytes typical of most nonvascular land plants.

Vascular plants allowed herbivores to colonize the land

The initial absence of herbivores (plant-eating animals) on land helped make the first vascular plants successful. By the late Silurian period (about 425 mya), vascular plants were being preserved as fossils that we can study today. The proliferation of these plants made the terrestrial environment more hospitable to animals. Arthropods, vertebrates, and other animals moved onto land only after vascular plants became established there.

Trees of various kinds appeared in the Devonian period and dominated the landscape of the Carboniferous period (359-299 mya). Forests of lycophytes (club mosses) up to 40 meters tall, along with horsetails and tree ferns, flourished in the tropical swamps of what would become North America and Europe ([Figure 27.12](#)). Plant material from those forests sank into the swamps and was gradually covered by layers of sediment. Over millions of years, as the buried plant material was subjected to intense pressure and elevated temperatures, it was transformed into coal. Today that coal provides more than 40 percent of the electricity generated worldwide. The world's coal deposits, although huge, are not infinite, and humans are burning coal deposits at a far faster rate than they were produced.

Figure 27.12 Artist's Reconstruction of an Ancient Forest Forests of the Carboniferous period were characterized by abundant vascular plants such as club mosses, ferns, and horsetails, some of which reached heights of 40 meters. Huge flying insects (see the opening of [Chapter 24](#)) thrived in these forests, which are the source of modern coal deposits.

In the subsequent Permian period, when the continents came together to form Pangaea, the continental interior became warmer and drier. The 200-million-year reign of the lycophyte-fern forests came to an end as they were replaced by forests of early gymnosperms.

The closest relatives of vascular plants lacked roots

The closest relatives of living vascular plants belonged to several extinct groups called rhyniophytes ([Figure 27.13](#)). The **rhyniophytes** were one of a very few types of land plants in the Silurian period. The landscape at that time probably consisted mostly of bare ground, with mats of nonvascular plants and stands of rhynio-phytes in low-lying moist areas. Early versions of the structural features of the vascular plant groups appeared in the rhyniophytes of that time. These shared features strengthen the case for the origin of all vascular plants from a common nonvascular land plant ancestor.

Figure 27.13 An Ancient Relative of the Vascular Plants The extinct rhyniophyte *Aglaophyton major* lacked roots and leaves. It had a central column of xylem running through its stems but no true tracheids. A horizontal underground stem called a rhizome anchored the plant. The dichotomously branching aerial stems were less than 50 centimeters tall. Some stems were topped by sporangia.

Rhyniophytes did not have roots. They were apparently anchored in the soil by horizontal portions of stem called **rhizomes**, which bore water-absorbing unicellular filaments called **rhizoids**. These plants also bore aerial branches, and sporangia—homologous to the sporangia of mosses—were found at the tips of those branches. The branching pattern of rhyniophytes was **dichotomous**; that is, the apex (tip) of the shoot divided to produce two equivalent new branches, with each pair of branches diverging at approximately the same angle from the original stem.

rhizome (rye' zome) An underground stem (as opposed to a root) that runs horizontally beneath the ground.

rhizoids (rye' zoids) [Gk. root] Hairlike extensions of cells in mosses, liverworts, and a few

vascular plants that serve the same function as roots and root hairs in vascular plants. The term is also applied to branched, rootlike extensions of some fungi and algae.

dichotomous (dye cot' oh mus) [Gk. *dichot*: split in two + *tomia*: removed) A branching pattern in which the shoot divides at the apex producing two equivalent branches that subsequently never overlap.

The lycophytes are sister to the other vascular plants

The club mosses and their relatives, the spike mosses and quillworts, are collectively called **lycophytes**. The lycophytes are the sister clade to the remaining vascular plants (see [Figure 27.1B](#)). There are relatively few (just over 1,200) surviving species of lycophytes.

The lycophytes have true roots that branch dichotomously. The arrangement of vascular tissue in their stems is simpler than in other vascular plants. They bear simple leaflike structures called **microphylls**, which are arranged spirally on the stem ([Figure 27.14A](#)). Growth in lycophytes comes entirely from apical cell division. Branching in the stems, which is also dichotomous, occurs by division of an apical cluster of dividing cells.

microphyll A small leaf with a single vein, found in club mosses and their relatives. (Contrast with megaphyll.)

(A) *Lycopodium digitatum*

(B) *Equisetum pratense*

(C) *Marsilea mutica*

(D) *Dicksonia* sp.

Figure 27.14 Lycophytes and Monilophytes **(A)** Club mosses have microphylls arranged spirally on their stems. Strobili are visible at the tips of these stems. **(B)** Horsetails have a distinctive growth pattern in which the stem grows in segments above each whorl of leaves. These are fertile shoots with sporangia-bearing structures at the apex. **(C)** The floating leaves of a water fern. **(D)** Tree ferns dominate this forest in Oparara Basin Kahurangi National Park in New Zealand.

The sporangia of many club mosses are aggregated in cone-like structures called **strobili** (singular *strobilus*; see [Figure 27.14A](#)), which are clusters of spore-bearing microphylls attached to the end of the stem. Other club mosses lack strobili and bear their sporangia on (or adjacent to) the upper surfaces of specialized microphylls.

Horsetails and ferns constitute a clade

The horsetails and ferns were once thought to be only distantly related. From analysis of gene sequences we now know that they form a clade, the **monilophytes**. In the monilophytes—as in the seed plants, to which they are the sister clade (see [Figure 27.1B](#))—the main stem is differentiated from side branches (including the leaves derived from these branches). This pattern contrasts with the dichotomous branching characteristic of the lycophytes and rhyniophytes, in which each split gives rise to two branches of similar size.

Today there are only about 15 species of **horsetails**, all in the genus *Equisetum*. The horsetails have reduced true leaves that form in distinct whorls (circles) around the stem ([Figure 27.14B](#)). Horsetails are sometimes called “scouring rushes” because rough silica deposits found in their cell walls make them useful for cleaning. They have true roots that branch irregularly. Horsetails have a large sporophyte and a small gametophyte, both independent of each other.

The first ferns appeared during the Devonian period; today this group comprises more than 12,000 species. Analyses of gene sequences indicate that a few species traditionally allied with ferns may in fact be more closely related to horsetails than to ferns. Nonetheless, the majority of ferns form a monophyletic group.

Although most ferns are terrestrial, a few species live in shallow fresh water ([Figure 27.14C](#)). Terrestrial ferns are characterized by large leaves with branching vascular strands ([Figure 27.14D](#)). Some fern leaves become climbing organs and may grow to be as long as 30 meters.

In the alternating generations of a fern, the gametophyte is small, delicate, and short-lived, but the sporophyte can be very large and can sometimes survive for hundreds of years ([Figure 27.15](#)). Ferns require liquid water for the transport of the male gametes to the female gametes, so most ferns inhabit shaded, moist woodlands and swamps. The sporangia of ferns are typically borne on a stalk in clusters called sori (singular *sorus*). The sori are found on the undersurfaces of the leaves, sometimes covering the entire undersurface and sometimes located at the edges.

Figure 27.15 Life Cycle of a Fern The most conspicuous stage in the fern life cycle is the mature diploid sporophyte, shown at the bottom of this diagram. The inset shows sori on the underside of a fern leaf. Each sorus contains many spore-producing sporangia.

Activity 27.1 The Fern Life Cycle www.Life11e.com/ac27.1

The vascular plants branched out

Several features that were new to the vascular plants evolved in lycophytes and monilophytes. Roots probably had their evolutionary origins as branches, either of a rhizome or of the aboveground portion of a stem. These branches presumably penetrated the soil and branched further. The underground portions could anchor the plant firmly, and even in this primitive

condition, they could absorb water and minerals.

The microphylls of lycophytes were probably the first leaflike structures to evolve among the vascular plants. Microphylls are usually small and only rarely have more than a single vascular strand, at least in existing species. Some biologists believe that microphylls had their evolutionary origins as sterile sporangia ([Figure 27.16A](#)). A typical feature of this type of leaf is a vascular strand that departs from the vascular system of the stem in such a way that the structure of the stem's vascular system is scarcely disturbed. This pattern was evident even in the lycophyte trees of the Carboniferous period, many of which had microphylls many centimeters long.

(A) Microphylls

(B) Megaphylls

Lycopodium (club moss)

Adiantum (fern)

Figure 27.16 Evolution of Leaves (A) Microphylls are thought to have evolved from sterile sporangia. **(B)** The megaphylls of monilophytes and seed plants may have arisen as photosynthetic tissue developed between branch pairs that were “left behind” as dominant branches overtopped them.

The monilophytes and seed plants constitute a clade called the **euphyllophytes** (*eu*, “true,” + *phyllon*, “leaf”). An important synapomorphy of the euphyllophytes is **overtopping**, a growth pattern in which one branch differentiates from and grows beyond the others (**Figure 27.16B**). Overtopping would have given these plants an advantage in the competition for light, enabling them to shade their dichotomously branching competitors. The overtopping growth of the euphyllophytes also allowed a new type of leaflike structure to evolve. This larger, more complex leaf is called a **megaphyll**. The megaphyll is thought to have arisen from the flattening of a portion of a branching stem system that exhibited overtopping growth. This change was followed by the development of photosynthetic tissue between the members of overtopped groups of branches, which had the advantage of increasing the photosynthetic surface area of those branches.

overtopping Plant growth pattern in which one branch differentiates from and grows beyond the others.

megaphyll The generally large leaf of a fern, horsetail, or seed plant, with several to many veins. (Contrast with microphyll.)

The first megaphylls, which were very small, appeared in the Devonian period. We might expect that evolution should have led swiftly to the appearance of more and larger megaphylls because of their greater photosynthetic capacity. However, it took some 50 million years, until the Carboniferous period, for large megaphylls to become common. Why should this have been so, especially given that other advances in plant structure were taking place during that time?

According to one theory, the high concentration of CO₂ in the atmosphere during the Devonian period reduced selection for the *stomata that allow a leaf to take up CO₂ for use in photosynthesis. With more CO₂ available, fewer stomata were needed. In the Devonian, larger leaves with a limited number of stomata would have absorbed heat from sunlight, but they would have been unable to lose heat fast enough by evaporation of water through their stomata. The resulting overheating would have been lethal. Recent research has supported this hypothesis, indicating that larger megaphylls evolved only as CO₂ concentrations dropped over millions of years ([Figure 27.17](#)).

Figure 27.17 Atmospheric CO₂ Concentrations and the Evolution of Megaphylls

Original Paper: Osborne, C. P., D. J. Beerling, B. H. Lomax and W. G. Chaloner. 2004. Biophysical constraints on the origin of leaves inferred from the fossil record. *Proceedings of the National Academy of Sciences USA* 101: 10360–10362.

High concentrations of atmospheric CO₂ during the first part of the Devonian may have limited the evolution of leaf size. C. P. Osborne and colleagues compared the leaf sizes of fossil plants against estimates of CO₂ concentrations in the atmosphere at the time the plants were alive.

HYPOTHESIS ▶ High atmospheric CO₂ concentrations during the early Devonian, and the resulting lack of selection for more stomata, kept leaf sizes small.

METHOD

1. Analyze 300 plant fossils from the Devonian and Carboniferous periods and measure the sizes of their leaves.
2. Compare the pattern of change in leaf size with that of the estimated change in atmospheric CO₂ concentrations over the same time span.

RESULTS

CONCLUSION ▶ Leaf size increased as levels of CO₂ in the atmosphere decreased.

Heterospory appeared among the vascular plants

In the lineages of present-day, seedless vascular plants that are most similar to their ancestors, the gametophyte and the sporophyte are independent, and both are usually photosynthetic. The spores produced by the sporophyte are of a single type and develop into a single type of gametophyte that bears both female and male reproductive organs (see [Figure 27.15](#)). Such plants, which bear a single type of spore, are said to be **homosporous** ([Figure 27.18A](#)).

homosporous Producing a single type of spore that gives rise to a single type of gametophyte, bearing both female and male reproductive organs. (Contrast with heterosporous.)

A system with two distinct types of spores evolved somewhat later. Plants of this type are said to be **heterosporous** ([Figure 27.18B](#)). In heterospory, one type of spore—the **megaspore**—develops into a specifically female gametophyte (a **megagametophyte**) that produces only eggs. The other type, the **microspore**, is smaller and develops into a male gametophyte (a **microgametophyte**) that produces only sperm. The sporophyte produces megaspores in small numbers in **megasporangia** and microspores in large numbers in **microsporangia**. Heterospory affects not only the spores and the gametophytes but also the sporophyte plant itself, which must develop two types of sporangia.

heterosporous (het' er os' por us) Producing two types of spores, one of which gives rise to a female megaspore and the other to a male microspore. (Contrast with homosporous.)

megaspore [Gk. *megas*: large + *spora*: to sow] In plants, a haploid spore that produces a female gametophyte.

megagametophyte In heterosporous plants, the female gametophyte; produces eggs. (Contrast with microgametophyte.)

microspore [Gk. *mikros*: small + *spora*: to sow] In plants, a haploid spore that produces a male gametophyte.

microgametophyte In heterosporous plants, the male gametophyte; produces sperm. (Contrast with megagametophyte.)

megasporangia The plant structures that bear megaspores.

microsporangia The plant structures that bear microspores.

(A) Homospory

Homosporous plants produce a single type of spore.

The spores of homosporous plants produce a single type of gametophyte with both male and female reproductive organs.

(B) Heterospory

Figure 27.18 Homospory and Heterospory (A) Homosporous plants bear a single type of spore. Each gametophyte has two types of sex organs, antheridia (male) and archegonia (female). **(B)** Heterosporous plants bear two types of spores that develop into distinctly male and female gametophytes.

Activity 27.2 Homospory www.Life11e.com/ac27.2

Activity 27.3 Heterospory www.Life11e.com/ac27.3

The earliest vascular plants were all homosporous, but heterospory evidently evolved several times independently among later groups of vascular plants. The fact that heterospory evolved repeatedly suggests that it affords selective advantages. Subsequent evolution in the land plants featured ever greater specialization of the heterosporous condition.

27.3 recap

Vascular plants are characterized by a vascular system specialized for the transport of materials from one part of the plant to another. A new type of cell, the tracheid, marked the origin of this group. Later evolutionary events included the appearance of roots, leaves, and heterospory.

learning outcomes

You should be able to:

- Explain the basic functions of vascular tissues.
- Describe important structures in vascular plants that probably first evolved in lycophytes.
- Compare possible selective advantages of heterospory over homospority.

1. How do the vascular tissues xylem and phloem serve the vascular plants?
2. Describe the evolution and distribution of different kinds of leaves and roots among the vascular plants.
3. Explain the concept of heterospory. How does heterospory provide selective advantages over homospority?

All of the vascular plant groups we have discussed thus far disperse by means of spores. The embryos of these seedless vascular plants develop directly into sporophytes, which either survive or die, depending on environmental conditions. The spores of some seedless plants may remain dormant and viable for long periods, but the embryos of seedless plants are relatively unprotected. Greater protection of the embryo evolved in the seed plants, which we will consider in the next chapter.

investigatinglife

QA Given that petroleum is derived naturally from green algae, can humans use green algae to produce oil commercially?

Scientists are developing new methods for growing green algae for the production of biofuels (fuels produced directly from living organisms, such as biodiesel). Some species of green algae can produce up to 60 percent of their dry weight in oil. So biofuels can certainly be produced from green algae, although the process is not yet commercially viable. Like conventional fossil fuels, biofuels release carbon dioxide into the atmosphere when burned. In the production of biofuels, however, algae remove carbon dioxide from the atmosphere, so the use of these fuels is more sustainable, and results in less accumulation of CO₂ in the atmosphere over time, than the use of fossil fuels.

Future directions

The primary commercial limitations to growing algae for biofuels include the need to establish efficient growing facilities, water needs, costs of fertilizers, costs and difficulties associated with harvest and refining, and labor expenses. As we explored in Investigating Life: Can *Chlorella* Algae Be Grown in Municipal Sewage Wastewater for Biofuel Production? considerable research is being conducted on ways to reduce these costs, such as growing algae for biofuels in municipal wastewater. Many new methods for growing and harvesting algae are being developed ([Figure 27.19](#)). Once some of the technical difficulties have been overcome, it is possible that commercial production of biofuels from algae will provide a significant source of energy for humans.

Figure 27.19 Biodiesel from Algae In this algal cultivation system for biofuel production, algae are grown in tubes of clear plastic.

► 27.1 Primary Endosymbiosis Produced the First Photosynthetic Eukaryotes

- Primary endosymbiosis gave rise to chloroplasts and the subsequent diversification of the **Plantae**. The descendants of the first photosynthetic eukaryote include **glaucoophytes**, **red algae**, several groups of green algae, and **land plants**, all of which contain chlorophyll *a*. **Review Figure 27.1**
- **Green plants**, which include the green algae and the land plants, are characterized by the presence of chlorophyll *b* (in addition to chlorophyll *a*). **Review Figure 27.1**
- Land plants, also known as **embryophytes**, arose from an aquatic green algal ancestor related to today's **stoneworts**. Land plants develop from embryos that are protected by parental tissue. **Review Figure 27.1**

► 27.2 Key Adaptations Permitted Plants to Colonize Land

- The acquisition of a cuticle, **stomata**, **gametangia**, a protected **embryo**, protective pigments, thick spore walls with a protective polymer, and mutualistic associations with fungi were all adaptations of land plants to terrestrial life.

stoma (plural: stomata) [Gk. *stoma*: mouth, opening] Small opening in the plant epidermis that permits gas exchange; bounded by a pair of guard cells whose osmotic status regulates the size of the opening.

embryo [Gk. *en*: within + *bryein*: to grow] A young animal, or young plant sporophyte, while it is still contained within a protective structure such as an egg, uterus, or seed.

- All land plant life cycles feature alternation of generations, in which a multicellular diploid **sporophyte** alternates with a multicellular haploid **gametophyte**. **Review Figure 27.6**

sporophyte (spor' o fyte) [Gk. *spora*: seed + *phyton*: plant] In plants and protists with alternation of generations, the diploid phase that produces the spores. (Contrast with gametophyte.)

gametophyte (ga meet' oh fyte) In plants and photosynthetic protists with alternation of generations, the multicellular haploid phase that produces the gametes. (Contrast with sporophyte.)

- The **nonvascular land plants** comprise the **liverworts**, **mosses**, and **hornworts**. These groups lack specialized vascular tissues for the conduction of water or nutrients through the plant body.

nonvascular land plants All land plants that lack a vascular system.

liver A large digestive gland. In vertebrates, it secretes bile and is involved in the formation of blood.

- The life cycles of nonvascular land plants depend on liquid water. The sporophyte is usually smaller than the gametophyte and depends on it for water and nutrition. Review [Figure 27.7](#), [Animation 27.1](#)
- Liverworts lack stomata, but they are present in mosses, hornworts, and vascular plants.
- Mosses have simple systems for the transport of water and sugars throughout the plant.
- Hornworts have a persistently green sporophyte, a characteristic shared with vascular plants. Hornworts also have a symbiotic relationship with cyanobacteria, which provide the hornworts with a usable form of nitrogen.

► 27.3 Vascular Tissues Led to Rapid Diversification of Land Plants

- The **vascular plants** have a vascular system consisting of [xylem](#) and [phloem](#) that conducts water, minerals, and products of photosynthesis through the plant body. The vascular system includes cells called [tracheids](#).

xylem (zy' lum) [Gk. *xylon*: wood] In vascular plants, the tissue that conducts water and minerals; xylem consists, in various plants, of tracheids, vessel elements, fibers, and other highly specialized cells.

phloem (flo' um) [Gk. *phloos*: bark] In vascular plants, the vascular tissue that transports sugars and other solutes from sources to sinks.

tracheid (tray' kee id) A type of tracheary element found in the xylem of nearly all vascular plants, characterized by tapering ends and walls that are pitted but not perforated. (Contrast with vessel element.)

- The **rhyniophytes**, the earliest known vascular plants, are known to us only in fossil form. They lacked true roots and leaves but possessed [rhizomes](#) and [rhizoids](#). Review [Figure 27.13](#)

rhizome (rye' zome) An underground stem (as opposed to a root) that runs horizontally beneath the ground.

rhizoids (rye' zoids) [Gk. *root*] Hairlike extensions of cells in mosses, liverworts, and a few vascular plants that serve the same function as roots and root hairs in vascular plants. The term is also applied to branched, rootlike extensions of some fungi and algae.

- The **lycophytes** (club mosses and relatives) have only small, simple leaflike structures ([microphylls](#)). **Monilophytes** (which include **horsetails** and ferns) have true leaves, and so together with seed plants are known as **euphyllophytes**.

microphyll A small leaf with a single vein, found in club mosses and their relatives. (Contrast with megaphyll.)

- Unlike in nonvascular land plants, the diploid sporophyte is the more conspicuous life stage of lycophytes and monilophytes. Review [Figure 27.15](#), [Activity 27.1](#)
- Microphylls probably evolved from sterile sporangia. [Megaphylls](#) (true leaves) may have resulted from the flattening and reduction of a portion of a stem system with [overtopping](#) growth. Review [Figure 27.16](#)

megaphyll The generally large leaf of a fern, horsetail, or seed plant, with several to many veins.

(Contrast with microphyll.)

overtopping Plant growth pattern in which one branch differentiates from and grows beyond the others.

- The earliest-diverging groups of vascular plants are [homosporous](#), but **heterospory**—the production of distinct [megaspores](#) and [microspores](#)—has evolved several times. Megaspores develop into female [megagametophytes](#); microspores develop into male [microgametophytes](#). Review [Figure 27.18](#), [Activities 27.2](#), [27.3](#)

homosporous Producing a single type of spore that gives rise to a single type of gametophyte, bearing both female and male reproductive organs. (Contrast with heterosporous.)

megaspore [Gk. *megas*: large + *spora*: to sow] In plants, a haploid spore that produces a female gametophyte.

microspore [Gk. *mikros*: small + *spora*: to sow] In plants, a haploid spore that produces a male gametophyte.

megagametophyte In heterosporous plants, the female gametophyte; produces eggs. (Contrast with microgametophyte.)

microgametophyte In heterosporous plants, the male gametophyte; produces sperm. (Contrast with megagametophyte.)

Review

- 7.1 Land plants fall into ten major clades.
- 7.2 The precursors of vascular plants are extinct.
- 7.3 Horsetails and ferns are more closely related than previously thought.

Original Paper: Kenrick, P. and P. R. Crane. 1997. The origin and early evolution of plants on land. *Nature* 389: 33-39.

Together, phylogenetic analysis and the fossil record reinforce each other in deepening our understanding of the evolution of taxa. The figure below shows the evolution of early land plants, reflecting the fossil record and phylogenetic relationships. Use the figure to answer the questions that follow.

Questions

1. About how long ago and in what geological period did the last common ancestor of ferns and seed plants live?
2. Spike mosses are a group of lycophytes, some species of which are popular for cultivation. If you saw fossils of spike mosses in a geological stratum, would you expect to find plants closely related to the last common ancestor of ferns and seed plants in the same rock formation? Explain. If not, would you expect to find the last common ancestor of ferns and seed plants in a higher or lower stratum?
3. If you saw rhyniophyte fossils in a geological stratum, would you expect to find plants closely related to the last common ancestor of ferns and seed plants in the same stratum? Explain.
4. About how long ago and in what geological period did the last common ancestor of embryophytes live? What significant change in the life history of plants occurred in this lineage?

***connect the concepts** As explained in [Key Concept 35.3](#), stomata are pores in the epidermis of plants that open and close to regulate uptake of CO₂ into the plant and guard against excessive diffusion of water out of the plant. Various environmental factors trigger the opening and closing of the stomata, including light, the CO₂ level in photosynthetic cells of the plant, and water availability.

The Evolution of Seed Plants

Phoenix dactylifera, the date palm, is widely cultivated for its edible fruit

key concepts

- [3.1 Pollen, Seeds, and Wood Contributed to the Success of Seed Plants](#)
- [3.2 Once Dominant Gymnosperms Still Thrive in Some Environments](#)
- [3.3 Flowers and Fruits Led to Increased Diversification of Angiosperms](#)
- [3.4 Plants Play Critical Roles in Terrestrial Ecosystems](#)

Brought Back from Extinction by a Seed

The Judean date is a fruit that was once much prized, admired for its nutritional and medicinal properties. This fruit was the source of the “honey” in the biblical “land of milk and honey.” Today that ancient strain of date is gone. Or is it?

About 2,000 years ago, a seed developed in a fruit on a Judean date palm. The fruit that contained that seed found its way to a storeroom in the fortress Masada in Judea. In 73 C.E. a band of Jewish zealots involved in a revolt against Rome fled to this refuge with their families and provisions. The fortress was eventually sacked and left in ruins.

Twenty centuries later, archeologists working in Masada discovered the date seed that was long ago stored in the Masada fortress and confirmed its age. The previous record for seed survival and germination was 1,300 years, held by lotus seeds that recently germinated under the care of scientists in China. But botanist Elaine Soloway succeeded in making the 2,000-year-old date seed germinate! For 10 years the seedling has thrived, and is now mature and producing pollen.

Seeds are important structures for the evolutionary survival of plants. Each seed protects an enclosed plant embryo from environmental extremes through what may be a very long and stressful resting period—in the case of the Judean date, many centuries in a harsh desert. Such hardiness has contributed to making seed plants the predominant plants on Earth. All of today’s forests are dominated by seed plants.

So will the resurrected palm serve as the parent of a new population of Judean dates, thus bringing that genotype back from extinction? Unfortunately, it cannot do so alone, because date palms have separate sexes, and the single known individual is a male that can only produce pollen. However, the search is on for other ancient seeds of Judean dates from archeological sites, and it is hoped that one of those will grow into a female plant that can produce new fruit and seeds. Even if a female Judean date seed cannot be found, the male Judean date’s pollen can be used to introduce valuable genes back into other, still living, strains of dates.

How long can most seeds survive, and why is seed dormancy important?

28.1 Pollen, Seeds, and Wood Contributed to the Success of Seed Plants

By the late Devonian period, more than 360 million years ago, Earth was home to a great variety of land plants, many of which we discussed in [Chapter 27](#). The land plants shared the hot, humid terrestrial environment with insects, spiders, centipedes, and early tetrapods. These plants and animals evolved together, each acting as agents of natural selection on the other.

focus your learning

Seed plants are heterosporous.

The seed is a well-protected resting stage.

Secondary growth increases the diameter of stems and roots in many seed plants.

In the Devonian, a new innovation appeared when some plants developed extensively thickened woody stems. Among the first plants with this adaptation were seedless vascular plants called **progymnosperms**, all species of which are now extinct. The pro-gymnosperms included many large trees.

Another innovation, the [seed](#), arose in the seed plants. Seeds provide a secure and lasting structure that protects the dormant stage of the embryo. A plant embryo may safely wait within its seed (in some cases for many years, or even centuries) until conditions are right for germination.

seed A fertilized, ripened ovule of a gymnosperm or angiosperm. Consists of the embryo, nutritive tissue, and a seed coat.

The earliest fossil evidence of seed plants is found in late Devonian rocks. Like the progymnosperms, these now-extinct [seed ferns](#) were woody. They possessed fernlike foliage but had seeds attached to their leaves. By the end of the Permian, other groups of seed plants had become dominant ([Figure 28.1](#)). Today's living seed plants fall into two major groups, the [gymnosperms](#) (such as pines and cycads) and the hugely diverse group known as the [angiosperms](#) (flowering plants).

seed A fertilized, ripened ovule of a gymnosperm or angiosperm. Consists of the embryo, nutritive tissue, and a seed coat.

gymnosperms Seed plants that do not produce flowers or fruits; one of the two major groups of living seed plants. (See *also* angiosperms.)

angiosperms Flowering plants; one of the two major groups of living seed plants. (See *also* gymnosperms.)

Figure 28.1 The Fossil Record of Seed Plant Evolution Woody growth evolved in the seedless progymnosperms. The now-extinct seed ferns had woody growth, fernlike foliage, and seeds attached to their leaves. New lineages of seed plants arose during the Carboniferous, but the earliest known fossils of flowering plants are from near the Jurassic-Cretaceous boundary. The flowering plants have dominated most terrestrial environments through the Cenozoic era.

Features of the seed plant life cycle protect gametes and embryos

In [Key Concept 27.2](#) we described a major trend in land plant evolution: the sporophyte became less dependent on the gametophyte, which became smaller in relation to the sporophyte. This trend continued with the seed plants, whose gametophyte generation is reduced even further than that of the ferns ([Figure 28.2](#)). The haploid seed plant gametophyte develops partly or entirely while attached to and nutritionally dependent on the diploid sporophyte.

Figure 28.2 The Relationship between Sporophyte and Gametophyte In the course of plant evolution, the gametophyte (brown) has been reduced and the

sporophyte (blue) has become more prominent.

Q: When you see a growing moss, are you more likely to see the haploid or the diploid multicellular stage? Is your answer the same for a fern and for a flowering plant?

Among the seed plants, only the earliest diverging groups of gym-nosperms (including modern cycads and ginkgos) have swimmingsperm. Even in these groups, sperm is transferred via pollen grains, so fertilization does not require liquid water outside the plant body. The evolution of pollen, along with the advent of seeds, gave seed plants the opportunity to colonize drier areas and spread over the terrestrial environment.

Seed plants are heterosporous (see [Figure 27.18B](#))—that is, they produce two types of spores, one that becomes a microgametophyte (male gametophyte) and one that becomes a megagametophyte (female gametophyte). These plants form separate microsporangia and megasporangia on structures that are grouped on short stems, such as the stamens and pistils of an angiosperm flower.

Within the microsporangium, the meiotic products are microspores. Within its spore wall, a microspore divides mitotically one or a few times to form a multicellular male gametophyte called a [pollen grain](#). Pollen grains are released from the microsporangium to be distributed by wind or by an animal pollinator ([Figure 28.3](#)). As in seedless land plants, the spore wall that surrounds the pollen grain contains sporopollenin, the most chemically resistant biological compound known, which protects the pollen grain against dehydration and chemical damage—another advantage in terms of survival in the terrestrial environment.

pollen grain [L. *pollin*: fine flour] In seed plants, microscopic grains that contain the male gametophyte (microgametophyte) and gamete (microspore).

Corylus avellana

Figure 28.3 Blown on the Wind Pollen grains are the male gametophytes of seed plants. The male flowers of this hazel tree release pollen-containing spores that are dispersed by the wind and may land near female gametophytes of other hazel plants.

 Media Clip 28.1 **Pollen Transfer by Wind** www.Life11e.com/mc28.1

In contrast to the microspores, the megaspores of seed plants are not shed. Instead, they develop into female gametophytes within the megasporangia. These megagametophytes are dependent on the sporophyte for food and water.

In most seed plant species, only one of the meiotic products in a megasporangium survives. The surviving haploid nucleus divides mitotically, and the resulting cells divide again to produce a multicellular female gametophyte. The megasporangium is surrounded by sterile sporophytic structures, which form an **integument** that protects the megasporangium and its contents. Together, the megasporangium and integument constitute the **ovule**, which will develop into a seed after fertilization.

integument [L. *integumentum*: covering] A protective surface structure. In gymnosperms and angiosperms, a layer of tissue around the ovule that will become the seed coat.

ovule (oh' vule) In plants, a structure comprising the megasporangium and the integument, which develops into a seed after fertilization.

The arrival of a pollen grain at an appropriate landing point, close to a female gametophyte on a sporophyte of the same species, is called **pollination**. A pollen grain that reaches this point develops further. It produces a slender **pollen tube** that elongates and digests its way toward the megagametophyte (**Figure 28.4**). When the tip of the pollen tube reaches the megagametophyte, sperm are released from the tube and fertilization occurs.

pollination The process of transferring pollen from an anther to the stigma of a pistil in an angiosperm or from a strobilus to an ovule in a gymnosperm.

pollen tube A structure that develops from a pollen grain through which sperm are released into the megagametophyte.

Figure 28.4 Pollination Is a Hallmark of the Seed Plants In most seed plants, a pollen tube grows from the pollen grain to the female gametophyte, where sperm are released and fertilize the egg within the ovule. Once fertilization takes place, the ovule can develop into a seed (see **Figure 28.5**). **(A)** Scanning electron micrograph of a pollen tube growing in the flower of an angiosperm, the prairie gentian. **(B)** The process of pollination is diagrammed for a generalized angiosperm flower.

Activity 28.1 Flower Morphology www.Life11e.com/ac28.1

The resulting diploid zygote divides repeatedly, forming an embryonic sporophyte. After a period of embryonic development, growth is temporarily suspended (the embryo enters a dormant stage). The end product at this stage is the multicellular seed.

The seed is a complex, well-protected package

A seed contains tissues from three generations (**Figure 28.5**). A seed coat develops from the

integument—the tissues of the diploid sporophyte parent that surround the megasporangium. Within the megasporangium is haploid tissue from the female gametophyte, which contains a supply of nutrients for the developing embryo. (This tissue is fairly extensive in most gymnosperm seeds. In angiosperm seeds it is greatly reduced, and nutrition for the embryo is supplied instead by a tissue called endosperm.) In the center of the seed is the third generation, the embryo of the new diploid sporophyte.

Figure 28.5 A Seed Develops These cross sections diagram the development of the ovule into a seed in a gymnosperm (*Pinus* sp.). Angiosperm seed development has differences (e.g., angiosperm integuments have two layers rather than one, and the angiosperm embryo is nourished by specialized tissue called endosperm) but follows the same principle (compare [Figures 28.8](#) and [28.16](#)). **(A)** The haploid megaspore is nourished by tissues of the parental sporophyte (the diploid megasporangium). **(B)** The mature megaspore is fertilized by a pollen grain that penetrates the integument, germinates (grows a pollen tube; see [Figure 28.4A](#)), and releases a sperm nucleus. **(C)** Fertilization initiates production of a seed. A mature seed contains three generations: a diploid embryo (the new sporophyte), which is surrounded by haploid female gametophyte tissue that supplies nutrition, which is in turn surrounded by the seed coat (diploid parental sporophyte tissue).

The seed is a well-protected resting stage. As we discussed in the opening of this chapter, the seeds of some species may remain dormant but stay viable (capable of growth and development) for many years, germinating only when conditions are favorable for the growth of the sporophyte. During the dormant stage, the seed coat protects the embryo from excessive drying and may also protect it against potential predators that would otherwise consume the embryo and its nutrient reserves. Many seed plants have structural adaptations that promote the dispersal of seeds by wind, water, or by animals. When the young sporophyte resumes growth, it draws on the food reserves in the seed. The possession of seeds is a major reason for the enormous evolutionary success of the seed plants, which are the dominant life forms of most modern terrestrial floras.

The germination of the Judean date described in the opening story is an extreme example of seed dormancy. How do we know how long most seeds remain viable? To find out, William J. Beal, a biologist at Michigan State University, decided to begin an experiment in 1879 that he could not hope to finish in his lifetime (**Investigating Life: William Beal's Seed Viability Study**). He prepared 20 lots of seeds for long-term storage. Each lot consisted of 50 seeds from each of 23 species of plants. He mixed each lot of seeds with sand and placed the mixture in an uncapped bottle, then buried all the bottles upside down (so they would stay dry) on a sandy

knoll. The seeds experienced normal temperature fluctuations for Michigan. At regular intervals ever since, other biologists have excavated a bottle and checked the viability of the seeds it contained. The seeds of most species remained viable for decades, whereas others have remained viable for more than a century.

investigatinglife William Beal's Seed Viability Study

experiment

William Beal began an experiment in 1879 to measure the long-term viability of seeds of several common plants. This ongoing experiment has been continued by biologists for well over a century. For the first 40 years of the experiment, Beal checked seed viability every 5 years. H. T. Darlington took over the experiment in 1915 and extended the sampling period to 10-year intervals beginning in 1920. R. S. Bandurski took over the experiment when Darlington retired, and extended the sampling period to 20 years in 1980, a century after the experiment began. Results for three species of plants in years 50–100 of the experiment are shown here.

QUESTION ▶ How long do seeds of common plants remain viable?

METHOD

1. Collect 1,000 seeds of each of 23 species of plants.
2. Divide the seeds into 20 lots of 50 seeds of each of the 23 species.
3. Mix each of the lots of seeds with sand, and place the mixtures in uncapped bottles.
4. Bury the bottles upside down (to prevent the entry of water) on a marked, sandy knoll.
5. At regular intervals, excavate a bottle and check the viability of its contents.

RESULTS

The table below shows the number of germinating seeds (of the original 50) from three of the species in years 50–100 of this ongoing experiment.

Species	Years after burial					
	50	60	70	80	90	100
<i>Oenothera biennis</i> (Evening primrose)	19	12	7	5	0	0
<i>Rumex crispus</i> (Curly dock)	26	2	7	1	0	0
<i>Verbascum blattaria</i> (Moth mullein)	31	34	37	35	10	21

CONCLUSION ▶ Biologists have used this and similar experiments to estimate the maximum viability of seeds of many species of plants under near-natural environmental conditions. Explore how these data can be used to make predictions about seed viability in the work with the data exercise.

work with the data

Use the data presented in the preceding experiment to answer the following questions.

QUESTIONS

1. Calculate the percent of viable seeds for these three species in years 50–100 and graph seed survivorship as a function of time buried.
2. No seeds of the first two species were viable after 90 years of the experiment. Assume 100 percent seed viability at the start of the experiment (year 0), and predict from your graph the approximate year when you think the last of the *Verbascum blattaria* seeds will germinate.
3. What factors do you think might influence the differences among the species in long-term seed viability?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

A change in stem anatomy enabled seed plants to grow to great heights

Fossils of the closest relatives of seed plants (progymnosperms) and the earliest seed plants (seed ferns) are found in late Devonian rocks (see [Figure 28.1](#)). These plants had thickened woody stems, developed through the proliferation of xylem. This type of growth, which increases the diameter of stems and roots in many modern seed plants, is called [secondary growth](#). Its product is secondary xylem, or wood.

secondary growth In plants, growth that contributes to an increase in girth. (Contrast with primary growth.)

The younger portion of the wood produced by secondary growth is well adapted for water transport, but older wood becomes clogged with resins or other materials. Although no longer functional in transport, the older wood continues to provide support for the plant. This support allows woody plants to grow taller than other plants around them and thus capture more light for photosynthesis.

Not all seed plants are woody. In the course of seed plant evolution, many groups lost the woody growth habit; however, other advantageous attributes helped them become established in an astonishing variety of places.

28.1 recap

Today's living seed plants fall into two major groups, the gymnosperms and the angiosperms. Pollen grains, seeds, and wood are major evolutionary innovations of the seed plants. Protection of embryos is a hallmark of seed plants.

learning outcomes

You should be able to:

- Explain how the evolution of pollen enabled seed plants to thrive in terrestrial environments.
 - Summarize the major advantages of having seeds.
 - Explain how seed plants altered the terrestrial landscape.
-
1. Explain the importance of pollen in freeing seed plants from dependence on liquid water.
 2. How do seeds and seed dormancy help plants survive in highly seasonal environments?
 3. What part did the evolution of wood play in changing the terrestrial landscape?

The seed ferns have long been extinct, but the surviving seed plants have been remarkable successes. After the seed ferns, the gymnosperms were the next group of plants to dominate terrestrial environments.

28.2 Once Dominant Gymnosperms Still Thrive in Some Environments

The gymnosperms are seed plants that do not form flowers or fruits. Gymnosperms (which means “naked-seeded”) are so named because their ovules and seeds, unlike those of angiosperms, are not protected by ovary or fruit tissue. Gymnosperms dominated the terrestrial world through the Mesozoic era but were replaced across large areas of Earth by flowering plants during the Cenozoic era (see [Figure 28.1](#)). Although there are now fewer than 1,200 living species of gymnosperms, these plants are still the primary forest trees in some areas.

focus your learning

Some pines are fire-adapted.

The reproductive structures of conifers are contained in male and female cones.

There are four major groups of living gymnosperms

The living gymnosperms can be divided into four major groups (see [Figure 27.1](#)):

- **Cycads** are palmlike plants of the tropics and subtropics ([Figure 28.6A](#)). Of the present-day gymnosperms, the cycads are probably the earliest-diverging clade. There are about 300 species, some of which grow as tall as 20 meters. The tissues of many species are highly toxic to humans if ingested.

(A) *Encephalartos* sp.

(B) *Ginkgo biloba*

(C) *Welwitschia mirabilis*

(D) *Pinus longaeva*

Figure 28.6 Diversity among the Gymnosperms (A) Many cycads have growth forms that resemble both ferns and palms, although cycads are not closely related to either group. (B) The characteristic broad leaves of the maidenhair tree. (C) The straplike leaves of *Welwitschia*, a gnetophyte, grow throughout the life of the plant, breaking and splitting as they grow. (D) Conifers dominate many types of landscapes in the Northern Hemisphere. Bristlecone pines such as these are the longest-lived individual trees known.

- **Ginkgos**, common during the Mesozoic era, are represented today by a single species, *Ginkgo biloba*, the maidenhair tree ([Figure 28.6B](#)). There are both male and female maidenhair trees. The difference is determined by X and Y sex chromosomes, as in humans; few other plants have distinct sex chromosomes.
- **Gnetophytes** number about 90 species in three very different genera, which share certain characteristics analogous to ones found in the angiosperms. One of the gnetophytes is *Welwitschia* ([Figure 28.6C](#)), a long-lived desert plant with straplike leaves that sprawl on the sand and can grow as long as 3 meters.
- **Conifers** are by far the most abundant of the gymnosperms. There are about 700 species of these cone-bearing plants, including the pines and redwoods ([Figure 28.6D](#)).

With the exception of the gnetophytes, the living gymnosperm groups have only tracheids as water-conducting and support cells within the xylem. Most gymnosperms lack the vessel elements and fibers (cells specialized for water conduction and support, respectively) that are found in angiosperms. While the gymnosperm water-transport and support system may seem somewhat less efficient than that of the angiosperms, it serves some of the largest trees known. The coastal redwoods of California are the tallest gymnosperms, with some individuals growing to well over 100 meters tall.

During the Permian, as environments became warmer and dryer, the conifers and cycads flourished. Gymnosperm forests changed over time as the gymnosperm groups evolved. Gymnosperms dominated the Mesozoic era, during which the continents drifted apart and large dinosaurs lived. Gymnosperms were the principal trees in all forests until about 65 million years ago, and even today conifers are the dominant trees in many forests, especially at high latitudes

and elevations. The oldest living single organism on Earth today is a gymnosperm in California—a bristlecone pine that germinated about 4,800 years ago, at about the time the ancient Egyptians were starting to develop writing (see [Figure 28.6D](#)).

Conifers have cones and lack swimming sperm

The great Douglas fir and cedar forests found in the northwestern United States and the massive boreal forests of pine, fir, and spruce of northern Eurasia and North America, as well as on the upper slopes of mountain ranges everywhere, rank among the great forests of the world. All these trees belong to one group of gymnosperms: the conifers, or cone-bearers.

Male and female **cones** contain the reproductive structures of conifers. The female (seed-bearing) cone is known as a **megastrobilus** (plural *megastrobili*). An example of a familiarmegastrobilus is the woody cone of pine trees. The seeds in a megastrobilus are protected by a tight cluster of woody scales, which are modifications of branches extending from a central axis ([Figure 28.7A](#)). The typically much smaller male (pollen-bearing) cone is known as a **microstrobilus**. The microstrobilus is typically herbaceous rather than woody, as its scales are composed of modified leaves, beneath which are the pollen-bearing microsporangia ([Figure 28.7B](#)).

cone In conifers, a reproductive structure consisting of spore-bearing scales extending from a central axis. (Contrast with strobilus.)

Figure 28.7 Female and Male Cones (A) The woody scales of female cones (megastrobili) are modified branches. **(B)** The herbaceous scales of male cones (microstrobili) are modified leaves.

The life cycle of a pine illustrates reproduction in gymnosperms ([Figure 28.8](#)). As in other seed plants, conifers have male gametophytes in the form of pollen grains, which frees the plants completely from their dependence on liquid water for fertilization. Wind assists conifer pollen grains in their first stage of travel from the microstrobilus to the female gametophyte inside a cone. A pollen tube provides the sperm with the means for the last stage of travel by elongating through maternal sporophytic tissue. When the pollen tube reaches the female gametophyte, it releases two sperm, one of which degenerates after the other unites with the egg. Union of sperm and egg results in a zygote. Mitotic divisions and further development of the zygote result in an embryo.

Figure 28.8 The Life Cycle of a Pine Tree In conifers and other gymnosperms, the gametophytes are small and nutritionally dependent on the sporophyte generation.

Animation 28.1 Life Cycle of a Conifer www.Life11e.com/a28.1

Activity 28.2 Life Cycle of a Conifer www.Life11e.com/ac28.2

The megasporangium, in which the female gametophyte will form, is enclosed in a layer of sporophytic tissue—the integument—that will eventually develop into the seed coat that protects the embryo. The integument, the megasporangium inside it, and the tissue attaching it to the maternal sporophyte constitute the ovule. The pollen grain enters through a small opening in the integument at the tip of the ovule, the **micropyle**.

micropyle (mike' roh pile) [Gk. *mikros*: small + *pylon*: gate] Opening in the integument(s) of a seed plant ovule through which pollen grows to reach the female gametophyte within.

Most conifer ovules, which will develop into seeds after fertilization, are borne exposed on the upper surfaces of the scales of the megastrobilus. The only protection of the ovules comes from the scales, which are tightly pressed against one another within the cone. Some pines, such as the lodgepole pine, have tightly closed cones that are sealed with resin. Fire is needed to melt the resin and open the cones to release the seeds. These species are said to be fire-adapted, and fire is essential to their reproduction. A fire devastated lodge-pole pine forests in Yellowstone National Park in 1988, but also released large numbers of seeds from cones. As a result, large numbers of lodgepole pine seedlings are now emerging in the burn area ([Figure 28.9](#)).

Figure 28.9 From Devastation, New Life A stand of lodgepole pines in Yellowstone National Park. The mature trees were destroyed by a forest fire in 1988. However, the fire released large numbers of seeds from cones, and now many young lodgepole pine trees are growing in the burn area.

About half of all conifer species have soft, fleshy tissues that envelop their seeds. Some of these are fleshy, fruitlike cones, as in junipers. Others are fruitlike extensions of the seeds, called arils, as in yews. These tissues, although often mistaken for “berries,” are not true fruits. As you will see in the next section, true fruits are the plant’s ripened ovaries, which are absent in gymnosperms. Nonetheless, the fleshy tissues that surround the seeds of many conifers serve a similar purpose as that of the fruits of flowering plants, acting as an enticement for seed-dispersing animals. Animals eat these fleshy tissues and disperse the seeds in their feces, often depositing the seeds considerable distances away from the parent plant.

Living gymnosperms can be divided into four major groups: cycads, ginkgos, gnetophytes, and conifers. Although they have declined since the Mesozoic era, gymnosperms are still the dominant trees in some areas, especially at high elevations and latitudes. All gymnosperms are woody and have seeds that are not protected by ovaries, although some have fleshy, fruitlike cones or extensions of seeds that entice animals to disperse the seeds.

learning outcomes

You should be able to:

- Describe and contrast the roles of male and female gametophytes in reproduction.
 - Summarize the functions of cones in conifers.
 - Describe the role of fire in the life history of the lodgepole pine.
-

1. How is fire necessary for the survival of some gymnosperms?
 2. Distinguish between the roles of the megagametophyte and the pollen grain in the life cycle of a conifer.
 3. What is the function of the fleshy cones that surround the seeds of many gymnosperms?
-

Although gymnosperms still dominate the terrestrial landscape in some environments, angiosperms (the flowering plants) have become the dominant land plants across much of the Earth.

28.3 Flowers and Fruits Led to Increased Diversification of Angiosperms

The most obvious feature defining the angiosperms is the **flower**, which is their sexual structure. Production of **fruits** is also a syn-apomorphy (shared derived trait) of angiosperms. After fertilization, the ovary of a flower (together with the seeds it contains) develops into a fruit that protects the seeds and can promote seed dispersal. As you will see, both flowers and fruits gave angiosperms major reproductive advantages that led to their dominance of the terrestrial environment in the Cenozoic era (see [Figure 28.1](#)).

flower The sexual structure of an angiosperm.

fruit In angiosperms, a ripened and mature ovary (or group of ovaries) containing the seeds. Sometimes applied to reproductive structures of other groups of plants.

focus your learning

In nearly all angiosperms, two male gametes, contained in a single microgametophyte, participate in fertilization.

Fruits are often specialized to encourage dispersal by animals, wind, or water.

All parts of a flower are modified leaves.

Angiosperms and their animal pollinators have been coevolving for more than 150 million years.

Angiosperms have many shared derived traits

The name *angiosperm* (“enclosed seed”) is derived from another distinctive trait of flowering plants that is related to the formation of fruits: the ovules and seeds are enclosed in a modified leaf called a **carpel**. Besides protecting the ovules and seeds, the carpel often interacts with incoming pollen to prevent self-pollination, thus favoring cross-pollination and increasing genetic diversity.

carpel (kar' pel) [Gk. *karpos*: fruit] The organ of the flower that contains one or more ovules.

The female gametophyte of the angiosperms is even more reduced than that of the gymnosperms, usually consisting of only seven cells (see [Figure 28.16](#)). Thus the angiosperms represent the current extreme of the trend we have traced throughout the evolution of the vascular plants: the sporophyte generation becomes larger and more independent of the gametophyte, while the gametophyte generation becomes smaller and more dependent on the sporophyte.

The xylem of most angiosperms is distinguished by the presence of specialized water-transporting cells called [vessel elements](#). These cells are larger in diameter than tracheids and connect with one another without obstruction, allowing easy water movement. A second distinctive cell type in angiosperm xylem is the [fiber](#), which plays an important role in supporting the plant body. The phloem of angiosperms possesses its own unique cell type, called a companion cell. Like the gymnosperms, woody angiosperms exhibit secondary growth, increasing in diameter by producing secondary xylem and secondary phloem.

vessel element A type of tracheary element with perforated end walls; found only in angiosperms. (Contrast with tracheid.)

fiber In angiosperms, an elongated, tapering sclerenchyma cell, usually with a thick cell wall, that serves a support function in xylem. (See *also* muscle fiber.)

A more comprehensive list of angiosperm synapomorphies, then, includes the following (some of these traits will be discussed later in this chapter):

Flowers

Fruits

Highly reduced female gametophytes

Ovules and seeds enclosed in a carpel

Germination of pollen on a stigma

Double fertilization

Endosperm (nutritive tissue for the embryo)

Phloem with companion cells?

The majority of these traits bear directly on angiosperm reproduction, which is a large factor in the success of this dominant plant group.

The sexual structures of angiosperms are flowers

Flowers come in an astonishing variety of forms—just think of a few of the flowers you recognize. Flowers may be single, or they may be grouped together to form an [inflorescence](#). Different families of flowering plants have characteristic types of inflorescences, such as the compound umbels of the carrot family ([Figure 28.10A](#)), the heads of the aster family ([Figure 28.10B](#)), and the spikes of many grasses ([Figure 28.10C](#)).

inflorescence A structure composed of several to many flowers.

(A) *Heracleum mantegazzianum*

(B) *Zinnia elegans*

(C) *Sorghum halepense*

Figure 28.10 Inflorescences (A) The inflorescence of the giant hog-weed, a member of the carrot family, is a compound umbel. Each umbel bears flowers on stalks that arise from a common center. (B) Zinnias are members of the aster family; their inflorescence is a head. Within the head, each of the long, petal-like structures is a ray flower; the central portion of the head consists of dozens to hundreds of disc flowers.

(C) Some grasses, such as Johnson grass, have inflorescences called spikes, which are composed of many smaller groups of flowers, or spikelets.

If you examine any familiar flower, you will notice that the outer parts look somewhat like leaves. In fact, all the parts of a flower are modified leaves. The diagram in [Figure 28.4B](#) represents a generalized flower (for which there is no exact counterpart in nature). The structures bearing microsporangia are called **stamens**. Each stamen is composed of a **filament** bearing an **anther** that contains the pollen-producing microsporangia. The structures bearing megasporangia are called carpels. A structure composed of one carpel or two or more fused carpels is called a **pistil**. The swollen base of the pistil, is called the **ovary**, which contains one or more ovules. Each ovule contains a megasporangium surrounded by two protective integuments. The apical stalk of the pistil is the **style**, and the terminal surface that receives pollen grains is the **stigma**.

stamen (stay' men) [L. *stamen*: thread] A male (pollen-producing) unit of a flower, usually composed of an anther, which bears the pollen, and a filament, which is a stalk supporting the anther.

filament In flowers, the part of a stamen that supports the anther.

anther (an' thur) [Gk. *anthos*: flower] A pollen-bearing portion of the stamen of a flower.

pistil [L. *pistillum*: pestle] The structure of an angiosperm flower within which the ovules are borne. May consist of a single carpel, or of several carpels fused into a single structure. Usually differentiated into ovary, style, and stigma.

ovary (oh' var ee) [L. *ovum*: egg] Any female organ, in plants or animals, that produces an egg.

style [Gk. *stēle*: pillar or column] In the angiosperm flower, a column of tissue extending from the tip of the ovary, and bearing the stigma or receptive surface for pollen at its apex.

stigma [L. *stigma*: mark, brand] The part of the pistil at the apex of the style that is receptive to pollen, and on which pollen germinates.

In addition, many flowers contain specialized sterile (non-spore-bearing) leaves. The inner ones are called **petals** (collectively, the corolla) and the outer ones **sepals** (collectively, the calyx). The corolla and calyx can be quite showy and often play roles in attracting animal pollinators to the flower. The calyx more commonly protects the immature flower in bud. From base to apex, these floral organs—sepals, petals, stamens, and carpels—are usually positioned in circular arrangements or whorls and attached to a central stalk.

petal [Gk. *petalon*: spread out] In an angiosperm flower, a sterile modified leaf, nonphotosynthetic, frequently brightly colored, and often serving to attract pollinating insects.

sepal (see' pul) [L. *sepalum*: covering] One of the outermost structures of the flower, usually protective in function and enclosing the rest of the flower in the bud stage.

The generalized flower in [Figure 28.4B](#) has both functional megasporangia and functional microsporangia; such flowers are referred to as **perfect** (or hermaphroditic). Many angiosperms produce two types of flowers, one with only megasporangia and the other with only microsporangia. Consequently, either the stamens or the carpels are nonfunctional or absent in a given flower, and the flower is referred to as **imperfect**.

Species such as corn or birch, in which both megasporangiate (female) and microsporangiate

(male) flowers occur on the same plant, are said to be **monoecious** (“one-housed”—but, it must be added, one house with separate rooms). Complete separation of imperfect flowers occurs in some other angiosperm species, such as willows and date palms; in these species, an individual plant produces either flowers with stamens or flowers with carpels, but never both. Such species are said to be **dioecious** (“two-housed”).

monoecious (mo nee’ shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in which both sexes are “housed” in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

dioecious (die eesh’ us) [Gk. *di*: two + *oikos*: house] Pertaining to organisms in which the two sexes are “housed” in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, date palms. (Contrast with monoecious.)

Flower structure has evolved over time

The flowers of the earliest-diverging clades of angiosperms have a large and variable number of tepals (undifferentiated sepals and petals), carpels, and stamens (**Figure 28.11A**). Evolutionary change within the angiosperms has included some striking modifications of this early condition: reductions in the number of each type of floral organ to a fixed number, differentiation of petals from sepals, and changes in symmetry from radial (as in a lily or magnolia) to bilateral (as in a sweet pea or orchid), often accompanied by an extensive fusion of parts (**Figure 28.11B**).

(A) *Nymphaea* sp.

(B) *Paphiopedilum* sp.

Figure 28.11 Flower Form and Evolution (A) A water lily shows the major features of early flowers: it is radially symmetrical, and the individual tepals, stamens, and carpels are separate, numerous, and attached at their bases. (B) Orchids such as this Venus slipper have a bilaterally symmetrical structure that evolved much later than radial flower symmetry.

According to one hypothesis, the first carpels to evolve were leaves with marginal sporangia, folded but incompletely closed. Early in angiosperm evolution, carpels fused with one another, forming a single, multichambered ovary ([Figure 28.12A](#)). In some flowers, the other floral organs are attached at the top of the ovary rather than at the bottom as in [Figure 28.4B](#). The stamens of the most ancient flowers may have been leaflike ([Figure 28.12B](#)), with little resemblance to the stamens of the generalized flower seen in [Figure 28.4B](#).

(A) Carpel evolution

(B) Stamen evolution

Figure 28.12 Carpels and Stamens Evolved from Leaflike Structures (A) Possible stages in the evolution of a carpel from a more leaflike structure. **(B)** The stamens of three modern plants show three possible stages in the evolution of that organ. (It is *not* implied that these species evolved from one another; their structures simply illustrate the possible stages.)

Why do so many flowers have pistils with long styles and anthers with long filaments? Natural selection has favored length in both of these floral organs, probably because length increases the likelihood of successful pollination. Long filaments may bring the anthers into contact with insect bodies, or they may place the anthers in a better position to catch the wind. Similar arguments apply to long styles.

A perfect flower represents a compromise of sorts. On the one hand, by attracting a pollinating bird or insect, the plant is attending to both its female and male functions with a single flower type, whereas plants with imperfect flowers must create that attraction twice—once for each type of flower. On the other hand, the perfect flower can result in self-pollination, which is usually disadvantageous. Another potential problem is that the female and male functions might interfere with each other—for example, the stigma might be placed so as to make it difficult for pollinators to reach the anthers, thus reducing the export of pollen to other flowers.

Might there be a way around these problems? One solution is seen in the bush monkeyflower (*Mimulus aurantiacus*), which is pollinated by hummingbirds. Its flower has a stigma that initially serves as a screen, hiding the anthers ([Figure 28.13](#)). Once a hummingbird touches the stigma, however, one of the stigma's two lobes is retracted, so that subsequent hummingbird visitors pick up pollen from the previously screened anthers. Thus the first bird to visit the flower transfers pollen from another plant to the stigma. Later visitors pick up pollen from the now-accessible anthers, fulfilling the flower's male function. [Figure 28.14](#) describes the experiment that revealed the function of this mechanism.

Figure 28.13 An Unusual Way to Prevent Selfing Both long stamens and long styles facilitate cross-pollination, but if these male and female structures are too close to each other, the likelihood of (disadvantageous) self-pollination increases. In *Mimulus aurantiacus*, the stigma is initially open, blocking access to the anthers. A hummingbird's touch as it deposits pollen on the stigma causes one lobe of the stigma to retract, creating a path to the anthers and allowing pollen dispersal by subsequent hummingbird visitors.

Figure 28.14 The Effect of Stigma Retraction in Monkeyflowers

Original Paper: Fetscher, A. E. 2001. Resolution of male-female conflict in an hermaphroditic flower. *Proceedings of the Royal Society B* 268: 525–528.

Elizabeth Fetscher's experiments showed that the unusual stigma retraction response to pollination in monkeyflowers (illustrated in Figure 28.13) enhances the dispersal of pollen to other monkeyflowers.

HYPOTHESIS▶ The stigma-retraction response in *M. aurantiacus* increases the likelihood that an individual flower's pollen will be exported to another flower once pollen from another flower has been deposited on its stigma.

METHOD

1. Set up three groups of monkeyflower arrays. Each array consists of one pollen-donor flower and multiple pollen-recipient flowers (with the anthers removed to prevent pollen donation).
2. In control arrays, the stigma of the pollen donor is allowed to function normally.
3. In one group of experimental arrays, the stigma of the pollen donor is permanently propped open (blocking access to the anthers).
4. In a second group of experimental arrays, the stigma of the pollen donor is artificially sealed closed (allowing access to the anthers).
5. Allow hummingbirds to visit the arrays, then count the pollen grains transferred from each donor flower to the recipient flowers in the same array.

RESULTS

Error bars indicate the standard errors of the mean.

CONCLUSION▶ The stigma-retraction response enhances the male function of the flower (dispersal of pollen) once the female function (receipt of pollen) has been performed.

Angiosperms have coevolved with animals

Whereas most gymnosperms are pollinated by wind, most angio-sperms are pollinated by animals. The many different ***mutualistic** pollination relationships between plants and animals are vital to both parties.

Many flowers entice animals to visit them by providing food rewards. Pollen grains themselves sometimes serve as food for animals. In addition, some flowers produce a sugary fluid called nectar, and some of these flowers have specialized structures to store and distribute it. In the process of visiting flowers to obtain nectar or pollen, animals often carry pollen from one flower to another or from one plant to another. Thus, in their quest for food, the animals contribute to the genetic diversity of the plant population. Insects, especially bees, are among the most important pollinators. Other major pollinators include some species of birds and bats.

Media Clip 28.2 **Pollen Transfer by a Bat** www.Life11e.com/mc28.2

For more than 150 million years, angiosperms and their animal pollinators have coevolved in the terrestrial environment. The animals have affected the evolution of the plants, and the plants have affected the evolution of the animals. Flower structure has become incredibly diverse under these selection pressures. Some of the products of coevolution are highly specific. For example, the flowers of some yucca species are pollinated by only one species of yucca moth, and that moth may exclusively pollinate just one species of yucca. Such specific relationships provide plants with a reliable mechanism for transferring pollen only to members of their own species.

Most plant-pollinator interactions are much less specific. In most cases, many different animal species pollinate the same plant species, and the same animal species pollinates many different plant species. However, even these less specific interactions have developed some specialization. Bird-pollinated flowers are often red and odorless. Many insect-pollinated flowers have characteristic odors. Bees see ultraviolet light well, so many bee-pollinated flowers have nectar guides that are visible in this region of the light spectrum (**Figure 28.15**).

Argentina anserina

Figure 28.15 See Like a Bee To normal human vision, the petals of silverweed appear solid yellow. Ultraviolet photography reveals patterns that attract bees to the central region, where pollen and nectar are located.

The fruits of some plants that are still around today originally evolved to attract large frugivorous animals—many of which went extinct in the Pleistocene. For example, the large round fruits of the osage orange tree attracted woolly mammoths, which ate the fruits and dispersed the seeds. After the extinction of the mammoths, osage orange trees survived in large part because early humans used the wood of this species for making bows for hunting, dispersing the fruits to new areas in the process. Some other species that depended on now-extinct mammals to disperse their seeds, however, may be slowly declining toward extinction.

The angiosperm life cycle produces diploid zygotes nourished by triploid endosperms

Like all seed plants, angiosperms are heterosporous. As you have seen, their ovules are contained within carpels rather than being exposed on the surfaces of scales, as in most gymnosperms. The male gametophytes, as in the gymnosperms, are pollen grains.

Pollination in the angiosperms consists of the arrival of a micro-gametophyte—a pollen grain—on a receptive surface in a flower (the stigma). As in the gymnosperms, pollination is the first in a series of events that results in the formation of a seed. The next event is the growth of a pollen tube extending to the megagametophyte. The third event is a fertilization process that, in detail, is unique to the angiosperms ([Figure 28.16](#)).

Figure 28.16 The Life Cycle of an Angiosperm Double fertilization results in triploid endosperm in most species of angiosperms. One sperm nucleus fertilizes the egg to form the zygote, while the other combines with the two polar nuclei to form the endosperm.

▶ Animation 28.2 **Life Cycle of an Angiosperm** www.Life11e.com/a28.2

In nearly all angiosperms, *two* male gametes, contained in a single microgametophyte, participate in fertilization. The nucleus of one sperm combines with that of the egg to produce a diploid zygote, the first cell of the sporophyte generation. In most angio-sperms, the other sperm nucleus combines with two other haploid nuclei of the female gametophyte to form a cell with a *triploid* (3n) nucleus. That cell, in turn, gives rise to triploid tissue, the **endo-sperm**, which nourishes the embryonic sporophyte during its early development. This process, in which two fertilization events take place, is known as **double fertilization**. In some angiosperms, additional haploid nuclei are incorporated to form even higher ploidy levels in the endosperm, or the second sperm fuses with only one haploid nucleus, resulting in diploid endosperm.

double fertilization In angiosperms, a process in which the nuclei of two sperm fertilize one egg. One sperm's nucleus combines with the egg nucleus to produce a zygote, while the other combines with the same egg's two polar nuclei to produce the first cell of the triploid

endosperm (the tissue that will nourish the growing plant embryo).

As [Figure 28.16](#) shows, the zygote develops into an embryo, which consists of an embryonic axis (the "backbone" that will become a stem and a root) and one or two [cotyledons](#), or "seed leaves." The cotyledons have different fates in different plants. In many, they serve as absorptive organs that take up and digest the endosperm. In others, they enlarge and become photosynthetic when the seed germinates. Often they play both roles.

cotyledon (kot' ul lee' dun) [Gk. *kotyledon*: hollow space] A "seed leaf." An embryonic organ that stores and digests reserve materials; may expand when seed germinates.

The ovule develops into a seed containing the products of the double fertilization that characterizes angiosperms: the diploid zygote and a triploid endosperm (see [Figure 28.16](#)). The endosperm serves as storage tissue for starch or lipids, proteins, and other substances that will be needed by the developing embryo.

Fruits aid angiosperm seed dispersal

Fruits often aid in seed dispersal. Fruits may attach to or be eaten by an animal. The animal is then likely to move, after which the seeds may fall off or be defecated. Fruits are not necessarily fleshy. Fruits can also be hard and woody, or small and have modified structures that allow the seeds to be dispersed by wind or water ([Figure 28.17](#)).

(A)

(B)

(C)

(D)

(E)

(F)

Figure 28.17 Fruits Come in Many Forms (A) The single seeds inside the simple fruits of Bing cherries are dispersed by animals. (B) Each seed of the horse chestnut is covered by a hard, woody fruit that allows it to survive drought. Although such fruits are commonly called “nuts,” this is a culinary rather than a biological term. (C) The highly reduced simple fruits of dandelions are dispersed by wind. (D) A multiple fruit, the pineapple (*Ananas comosu*), has become one of the most economically significant fruit crops of the tropics. (E) An aggregate fruit (blackberry). (F) An accessory fruit (pear).

Q: The large incisors of rodents help these animals penetrate the shells of woody nuts, which they consume as food. But unlike many animals that eat fruits without digesting the seeds, rodents destroy the seeds when they eat them. So how do rodents aid in dispersing the seeds of nut-bearing plants?

A fruit may consist of only the mature ovary and its seeds, or it may include other parts of the flower or structures associated with it. A **simple fruit** is one that develops from a single carpel or several fused carpels, such as a plum or cherry. A raspberry is an example of an **aggregate fruit**—one that develops from several separate carpels of a single flower. Pineapples and figs are examples of **multiple fruits**, formed from a cluster of flowers (an inflorescence). Fruits derived from parts in addition to the carpel and seeds are called **accessory fruits**—examples are apples, pears, and strawberries.

simple fruit A fruit that develops from a single carpel in a single flower.

aggregate fruit A fruit that develops from several carpels from the same flower.

multiple fruits A fruit that develops from several carpels of multiple flowers.

accessory fruits A fruit in which some of the flesh develops from tissue exterior to the carpel.

Media Clip 28.3 Flower and Fruit Formation www.Life11e.com/mc28.3

Recent analyses have revealed the phylogenetic relationships of angiosperms

Figure 28.18 shows the relationships among the major angiosperm clades. Recent molecular and morphological analyses have supported the hypothesis that the sister group of remaining flowering plants is a single species of the genus *Amborella* (**Figure 28.19A**). This woody shrub with cream-colored flowers lives only on New Caledonia, an island in the South Pacific. Other early-branching angiosperm groups include the water lilies (**Figure 28.19B**), star anise and its relatives (**Figure 28.19C**), and the **magnoliids** (**Figure 28.19D,E**). The magnoliids include many familiar and useful plants, such as avocados, cinnamon, black pepper, and magnolias.

Figure 28.18 Evolutionary Relationships among the Angiosperms Recent analyses of many angiosperm genes have clarified the relationships among the major groups.

(D) *Magnolia* sp.

(E) *Aristolochia ringens*

Figure 28.19 Monocots and Eudicots Are Not the Only Surviving Angiosperms

(A) *Amborella*, a shrub, is sister to the remaining extant angiosperms. Notice the sterile stamens on this female flower, which may serve to lure insects that are searching for pollen. (B) The water lily clade was the next to diverge after *Amborella*. (C) Star anise and its relatives belong to another early-diverging angiosperm clade. (D, E) The largest clade other than the monocots and eudicots is the magnoliid complex, which includes magnolias and the group known as “Dutchman’s pipe.”

The two largest clades—the **monocots** and the **eudicots**—include the great majority of angiosperm species. The monocots are so called because they have a single embryonic cotyledon, whereas the eudicots have two.

monocots Angiosperms with a single embryonic cotyledon; one of the two largest clades of angiosperms. (See *also* eudicots.)

eudicots Angiosperms with two embryonic cotyledons. (See *also* monocots.)

Representatives of the two largest angiosperm clades are everywhere. The monocots (**Figure 28.20**) include grasses, cattails, lilies, orchids, and palms. The eudicots (**Figure 28.21**) include the vast majority of familiar seed plants, including most herbs (i.e., nonwoody plants), vines, trees, and shrubs. Among the eudicots are such diverse plants as oaks, willows, beans, snapdragons, roses, and sunflowers.

(A) *Tulipa* sp. and *Narcissus* sp.

(B) *Oryza sativa*

(C) *Posidonia oceanica*

(D) *Phoenix dactylifera*

Figure 28.20 Monocots (A) Monocots include many popular garden flowers such as

these tulips (pink and white) and daffodils (yellow). **(B)** Monocot grasses such as rice feed the world; wheat, sugarcane, and corn (maize) are also grasses. **(C)** Seagrasses such as this Neptune's grass form "meadows" in the shallow, sunlit waters of the world's oceans. **(D)** Palms are among the few monocot trees. Date palms like these are a major food source in some areas of the world.

(A) *Malus* sp.

(B) *Banksia coccinea*

(C) *Escobaria vivipara*

(D) *Rafflesia arnoldii*

Figure 28.21 Eudicots (A) Eudicots include many trees, such as this crabapple tree. (B) Scarlet Banksia is a species of an Australian genus of eudicots that attracts a wide diversity of pollinators by producing large quantities of nectar. (C) Cacti comprise a large group of eudicots, with about 1,500 species in the Americas. Many, such as this spiny star cactus, bear large flowers for a brief period of each year. (D) *Rafflesia arnoldii*, found in the rainforests of Indonesia, bears the largest flower in the world. The flower lives as a parasite on tropical vines and has lost its leaf, stem, and even root structures. It smells like decaying meat, which attracts its fly pollinators.

28.3 recap

Angiosperms are the dominant terrestrial plants of the Cenozoic era. The synapomorphies of angiosperms include flowers, fruit, carpels, double fertilization, and endosperm. Most angiosperms also possess distinctive cells in the xylem and phloem. The largest angiosperm clades are the monocots and the eudicots.

learning outcomes

You should be able to:

- Distinguish between the two different roles of sperm in angiosperm double fertilization.
- Distinguish between pollination and fertilization.
- Make inferences about the likely modes of seed dispersal based on the type of fruit the plant produces.
- Compare the functions of flowers, fruits, and seeds.

1. What are the respective roles of the two sperm in double fertilization in angiosperms?
2. Explain the difference between pollination and fertilization.
3. What are some of the differences between fruits that are dispersed by attracting animals to a food resource and those that are dispersed by attaching themselves to animals? Give examples of each.

4. What are the different functions of flowers, fruits, and seeds?

The remarkable diversity of the seed plants has been shaped by both biotic and abiotic components of the environments to which they have adapted. In turn, land plants—and seed plants in particular—shape their environments.

***connect the concepts** Mutualisms benefit both partners in a relationship, as described in [Chapter 55](#).

28.4 Plants Play Critical Roles in Terrestrial Ecosystems

Plants make profound contributions to ecosystem services — processes by which the environment maintains resources that benefit human society. Once life moved onto land, it was largely plants that shaped the terrestrial environment.

focus your learning

Plants make profound contributions to ecosystem services.

Many medicines are derived from seed plants

Most of the food eaten by humans comes from only 12 species of seed plants.

Plants produce oxygen and remove carbon dioxide from the atmosphere, and they play important roles in forming soils and renewing soil fertility. Plant roots help hold soil in place, providing protection against erosion by wind and water ([Figure 28.22](#)). Plants also moderate the local climate in various ways, such as by increasing humidity, providing shade, and blocking wind. All of these ecosystem services permit a great diversity of fungi and animals to exist on land.

Figure 28.22 Plants Prevent Erosion When forest vegetation was cleared on these hillsides in Malaysia, landslides and extensive soil erosion quickly followed. Adjacent forested areas did not have landslides.

Seed plants have been sources of medicine since ancient times

Although we also use medicines derived from fungi, lichens, and actinobacteria, seed plants are

the source of many of our medications. A few examples of medicines derived from plants are shown in [Table 28.1](#). Even in synthetic pharmaceuticals, the chemical structures of the active ingredients are often based on the biochemistry of substances isolated from plants.

table 28.1 Some Medicinal Plants and Their Products		
Product	Plant source	Medical application
Atropine	Belladonna	Dilate pupils for eye examination
Bromelain	Pineapple stem	Control tissue inflammation
Digitalin	Foxglove	Strengthen heart muscle contraction
Ephedrine	<i>Ephedra</i>	Ease nasal congestion
Menthol	Japanese mint	Relieve coughing
Morphine	Opium poppy	Relieve pain
Quinine	<i>Cinchona</i> bark	Treat malaria
Taxol	Pacific yew	Treat ovarian and breast cancers
Tubocurarine	Curare plant	Muscle relaxant (used in surgery)
Vincristine	Periwinkle	Treat leukemia and lymphoma

How are plant-based medicines discovered? Many were discovered over the millennia by people who lived alongside useful plants and discovered the properties of the plants through trial and error. Some plant-based medicines have come into widespread use through the work of ethnobotanists, who study how people use and view plants in their local environments. This work proceeds all over the globe today. An older example of this approach is the discovery of quinine as a treatment for malaria. In the sixteenth century, Spanish priests in Peru became aware that the native population used the bark of local *Cinchona* trees to treat fevers. The priests successfully used the bark to treat malaria. Word of the medicine spread to Europe, where it was put into use as early as 1631. The active ingredient of *Cinchona* bark—quinine—was identified in 1820, and quinine remained the standard malarial remedy well into the twentieth century.

Since the mid-1900s, many plant-based medicines have been found by systematic testing of plants from all over the world. One example of a medicine discovered in this way is taxol, an important anticancer drug. Among the myriad plant samples that had been tested by 1962, extracts of the bark of the Pacific yew (*Taxus brevifolia*) showed anti-tumor activity in tests against rodent tumors. The active ingredient, taxol, was isolated in 1971 and tested against human cancers in 1977. After another 16 years, the U.S. Food and Drug Administration approved it for human use, and taxol is now widely used in treating breast and ovarian cancers as well as several other types of cancers.

Seed plants are our primary food source

Plants are primary producers. They trap energy and carbon by means of photosynthesis, making those resources available not only for their own needs, but also for the herbivores and omnivores that consume them, for the carnivores and omnivores that eat the herbivores, and for the prokaryotes and fungi that complete food webs. The earliest steps in human civilization involved cultivating angiosperms to provide a reliable food supply.

Today, twelve species of seed plants account for most of the food eaten by humans: rice, coconut, wheat, corn (maize), potato, sweet potato, cassava (also called tapioca or manioc), sugarcane, sugar beet, soybean, common bean (*Phaseolus vulgaris*), and banana. Hundreds of other seed plants are cultivated for food, but none rank with these twelve in importance. Indeed, more than half of the world's human population derives the bulk of its food energy from the

seeds of a single plant, *Oryza sativa*, better known as rice. Rice is particularly important in eastern Asia, where it has been cultivated for more than 8,000 years ([Figure 28.23](#)).

Figure 28.23 Rice Feeds Much of the World’s Human Population These rice fields, or “paddies,” are in south China. Rice has been cultivated in this manner for thousands of years.

In addition to providing food directly for human consumption, plants also provide feed for agricultural production of animals. In particular, the grasses that grow in the world’s rangelands are the primary forage for the grazing animals that humans use for meat and dairy products.

28.4 recap

Terrestrial ecosystems could not function without the foods and habitats provided by plants. Plants produce oxygen and remove carbon dioxide from the atmosphere, help form soils, and hold soils in place against erosion by wind and water. Plants also provide us with many important medicines and are the basis (directly or indirectly) of virtually all of our food.

learning outcomes

You should be able to:

- Describe how seed plants have been used for medicinal purposes.
- Summarize the ecological services angiosperms perform.
- Summarize the main plants humans use for food.

1. Name three plants that are used in medicine for humans, and give an example of how each is used.
2. A parcel of agricultural land that has been used to produce corn for decades no longer produces healthy crops. Tests indicate that the soil is depleted of nitrogen and organic matter. A farm extension agent recommends that the farmer grow soybeans and then rotate this crop with corn in future years. She also recommends that the farmer till the stubble from the crops after harvest into the soil. Why are these practices expected to help

crop production?

3. What major group of plants provides (either directly or indirectly) the majority of calories consumed by humans? Explain your answer.

▶ investigatinglife

QA How long can most seeds survive, and why is seed dormancy important?

As you saw in Investigating Life: William Beale's Seed Viability Study and in the opening of this chapter, seeds of some plants can remain dormant but viable for decades, centuries, or in extreme cases, even millennia. Seed dormancy is especially important for the long-term survival of plant species that grow in unpredictable or highly fluctuating environments. If the appropriate conditions for seed growth and seedling maturation occur only rarely, then seeds need to be able to remain dormant in the soil until those favorable conditions occur. Biologists refer to dormant seeds in a given area as the "seed bank." What conditions will cause the seeds to break their dormancy and sprout? Fire, heavy rain, appropriate temperatures, or disturbance by animals are some of the more common stimulants for breaking seed dormancy. Many seeds need to be consumed by an animal and pass through the acidic conditions of the animal's digestive system before the seeds will sprout. As anyone who has planted a new garden will know, soil disturbance will often produce the conditions needed for many dormant seeds to start growing. A new garden often requires persistent weeding to remove all the unwanted (by the gardener) plants that have been "awakened" from the seed bank.

Future directions

We've noted that humans depend on a relatively small number of plants for the majority of our food needs, although many more species of plants are grown and eaten for food. Traditionally, different locally adapted strains of crop plants have been grown by different farmers in different regions of the world. Agricultural companies now produce new varieties of crops that increase agricultural production. Unfortunately, a downside to these new strains is that farmers across the world have switched to growing relatively few varieties of important crop plants, which increases our global risk to disease and pests. If all farmers grow the same strain of wheat, for example, and that strain is susceptible to a particular pathogen or insect pest, what happens when the pathogen or pest spreads and all the susceptible wheat is lost?

To guard against devastating losses of important plants, many nations around the world have collaborated to develop a secure seed vault, which stores and protects the genetic diversity of crop plants ([Figure 28.24](#)). This seed vault is built into a sandstone mountain, surrounded by permafrost on the Arctic island of Spitsbergen, Norway. It is situated at a high enough elevation that it will remain above sea level even if all the polar ice caps were melted by global warming. Cooling systems maintain the vault at -18°C , and even if these systems fail, insulation and local cold weather would protect the seeds inside and maximize their viability. This seed vault complements several shorter-term seed depositories that are maintained in individual countries. Such seed depositories are used by biologists to develop new varieties of plant crops and to research the genetic variation of plant species from around the world.

Figure 28.24 The Global Seed Vault This vault is located over 100 meters inside a sandstone mountain on the Norwegian island of Spitsbergen, about 1,000 kilometers from the North Pole. The location was chosen for secure, long-term storage of seeds because the surrounding ground is perpetually frozen and the site is secure against earthquakes, floods, and other natural disasters.

► 28.1 Pollen, Seeds, and Wood Contributed to the Success of Seed Plants

- Fossils of woody seed ferns are the earliest evidence of seed plants. The surviving groups of seed plants are the [gymnosperms](#) and [angiosperms](#). **Review Figure 28.1**

gymnosperms Seed plants that do not produce flowers or fruits; one of the two major groups of living seed plants. (See *also* angiosperms.)

angiosperms Flowering plants; one of the two major groups of living seed plants. (See *also* gymnosperms.)

- All seed plants are heterosporous, and their gametophytes are much smaller than (and dependent on) their sporophytes. **Review Figure 28.2**
- Seed plants do not require liquid water for fertilization. [Pollen grains](#), the microgametophytes of seed plants, are carried to a megagametophyte by wind or by animals.

pollen grain [L. *pollin*: fine flour] In seed plants, microscopic grains that contain the male gametophyte (microgametophyte) and gamete (microspore).

- An [ovule](#) consists of the seed plant megagametophyte and the [integument](#) of sporophytic tissue that protects it.

ovule (oh' vule) In plants, a structure comprising the megasporangium and the integument, which develops into a seed after fertilization.

integument [L. *integumentum*: covering] A protective surface structure. In gymnosperms and angiosperms, a layer of tissue around the ovule that will become the seed coat.

- Following [pollination](#), a **pollen tube** emerges from the pollen grain, elongates, and usually delivers gametes to the megagametophyte. **Review Figure 28.4, Activity 28.1**

pollination The process of transferring pollen from an anther to the stigma of a pistil in an angiosperm or from a strobilus to an ovule in a gymnosperm.

- The ovule develops into a [seed](#) that contains an embryo (the new sporophyte generation). Seeds are well protected and are often capable of long periods of dormancy, germinating only when conditions are favorable. **Review Figure 28.5**

seed A fertilized, ripened ovule of a gymnosperm or angiosperm. Consists of the embryo, nutritive tissue, and a seed coat.

▶ 28.2 Once Dominant Gymnosperms Still Thrive in Some Environments

- Gymnosperms were the dominant terrestrial plants of the Mesozoic era. Although they declined in the Cenozoic era, they continue to thrive today in some areas—especially in high-elevation and high-latitude forests.
- The gymnosperms produce ovules and seeds that are not protected by ovary or fruit tissues.
- The major gymnosperm groups are the **cycads**, **ginkgos**, **gneto-phytes**, and **conifers**.
Review [Figure 28.6](#)
- The megaspores of conifers are produced in woody **cones** called **megastrobili**; the microspores are produced in herbaceous cones called **microstrobili**.
Review [Figures 28.7, 28.8, Activity 28.2, Animation 28.1](#)

cone In conifers, a reproductive structure consisting of spore-bearing scales extending from a central axis. (Contrast with strobilus.)

▶ 28.3 Flowers and Fruits Led to Increased Diversification of Angiosperms

- Angiosperms are the dominant plants of the Cenozoic era (the most recent 65 million years of Earth's history).
- **Flowers and fruits** are unique to the angiosperms, distinguishing them from the gymnosperms.

flower The sexual structure of an angiosperm.

- The xylem of most angiosperms is more complex than that of the gymnosperms. It contains two specialized cell types: **vessel elements**, which function in water transport, and **fibers**, which play an important role in structural support.

vessel element A type of tracheary element with perforated end walls; found only in angiosperms. (Contrast with tracheid.)

fiber In angiosperms, an elongated, tapering sclerenchyma cell, usually with a thick cell wall, that serves a support function in xylem. (See *also* muscle fiber.)

- The ovules and seeds of angiosperms are enclosed in and protected by **carpels**.

carpel (kar' pel) [Gk. *karpos*: fruit] The organ of the flower that contains one or more ovules.

- The floral organs, from the base to the apex of the flower, are the **sepals**, **petals**, **stamens**, and **pistil**. Stamens bear microsporangia in anthers. The pistil (consisting of one or more carpels) includes an **ovary** containing ovules. The **stigma** is the receptive surface of the pistil for pollen.

sepal (see' pul) [L. *sepalum*: covering] One of the outermost structures of the flower, usually protective in function and enclosing the rest of the flower in the bud stage.

pistil [L. *pistillum*: pestle] The structure of an angiosperm flower within which the ovules are borne. May consist of a single carpel, or of several carpels fused into a single structure. Usually

differentiated into ovary, style, and stigma.

ovary (oh' var ee) [L. *ovum*: egg] Any female organ, in plants or animals, that produces an egg.

stigma [L. *stigma*: mark, brand] The part of the pistil at the apex of the style that is receptive to pollen, and on which pollen germinates.

- A flower with both megasporangia and microsporangia is referred to as **perfect**; a flower with only one or the other is **imperfect**.
- A **monoecious** species has megasporangiate and microsporangiate flowers on the same plant. A **dioecious** species is one in which megasporangiate and microsporangiate flowers occur on different plants.

monoecious (mo nee' shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in which both sexes are "housed" in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

dioecious (die eesh' us) [Gk. *di*: two + *oikos*: house] Pertaining to organisms in which the two sexes are "housed" in two different individuals, so that eggs and sperm are not produced in the same individuals. Examples: humans, fruit flies, date palms. (Contrast with monoecious.)

- The carpels and stamens of flowers probably evolved from leaflike structures. **Review Figure 28.12**
- Some plants with perfect flowers have adaptations to prevent self-fertilization. **Review Figure 28.13**
- Many angiosperms have coevolved with their animal pollinators.
- Angiosperms exhibit **double fertilization**, usually resulting in the production of a diploid zygote and triploid **endosperm**. **Review Figure 28.16, Animation 28.2**

double fertilization In angiosperms, a process in which the nuclei of two sperm fertilize one egg. One sperm's nucleus combines with the egg nucleus to produce a zygote, while the other combines with the same egg's two polar nuclei to produce the first cell of the triploid endosperm (the tissue that will nourish the growing plant embryo).

endosperm [Gk. *endo*: within + *sperma*: seed] A specialized triploid seed tissue found only in angiosperms; contains stored nutrients for the developing embryo.

- The oldest evolutionary split among the angiosperms is between the clade represented by the single species in the genus *Amborella* and all the remaining flowering plants. **Review Figure 28.18**
- The most species-rich angiosperm **clades are the monocots and the eudicots**.

► 28.4 Plants Play Critical Roles in Terrestrial Ecosystems

- Plants provide critical ecosystem services that affect soil, water, air quality, and climate.
- Plants provide humans with many important medicinal products.
- Plants are primary producers and as such are the foundation of terrestrial food webs.

Review

8.3 All parts of a flower are modified leaves.

8.3 Angiosperms and their animal pollinators have been coevolving for more than 150 million years.

Original Paper: Schemske, D. W. and H. D. Bradshaw, Jr. 1999. Pollinator preference and the evolution of floral traits in monkeyflowers (*Mimulus*). *Proceedings of the National Academy of Sciences USA* 96: 11910-11915.

M. lewisii

M. cardinalis

Recent studies show that switches in pollinators and large changes in flower morphology can evolve quickly. In the photographs at right, the *Mimulus* species are excellent examples of such changes. Despite being sufficiently closely related that they hybridize readily in the lab, these species differ greatly in morphology and color. They also differ in their pollinators, with *M. cardinalis* pollinated exclusively by hummingbirds and *M. lewisii* pollinated primarily by bees and other insects. (Note that other species may visit the flowers, but not pollinate them).

Questions

1. Given their pollinators, are the floral colors of the two species what you would expect? Explain your answer.
2. What differences are apparent between the flower corollas in the two species? Present a reasonable explanation for these differences, based on the pollinator differences.
3. Researchers found that variation at a single locus (called *yup*) was responsible for the color differences and that the *M. cardinalis* allele (C) is recessive, whereas the *M. lewisii* allele (L) is dominant. Thus CC genotypes are red, while both LL and LC genotypes are light pink. The researchers then examined the preferences of bees and humming-birds for the different genotypes at the *yup* locus, keeping the rest of the genetic background of the plant the same. Their findings are shown at right. (Remember, these are visitation rates, not necessarily pollination rates.)

Based on these results, how does variation at the *yup* locus affect visitation by bees and hummingbirds?

1. Do the results presented in Question 3 show a significant preference for red or pink flowers by birds and bees, respectively? Given your answer, why do you think most bird-pollinated flowers are red?

The Accidental Discovery of Antibiotics

Alexander Fleming was already a famous scientist in 1928, but his laboratory was often a mess. That year he was studying the properties of *Staphylococcus* bacteria, the agents of dangerous staph infections. In August he took a long vacation with his family. When he returned in early September, he found that some of his petri dishes of *Staphylococcus* had become infested with a fungus that killed many of the bacteria.

Many scientists would have sighed at the loss, thrown out the petri dishes, and started new cultures of bacteria. But when Fleming looked at the dishes, he saw something exciting. Around each colony of fungi was a ring within which all the bacteria were dead.

Fleming hypothesized that the bacteria-free rings around the fungal colonies were produced by a substance excreted from the fungi, which he initially called “mould juice.” He identified the fungi as members of the genus *Penicillium* and eventually named the antibacterial substance they produced “penicillin.” Fleming published his discovery in 1929, but initially it received very little attention.

Over the next decade, Fleming produced small quantities of penicillin for testing as an antibacterial agent. Some of the tests showed promise, but many were inconclusive, and eventually Fleming gave up on the research. But his tests had shown enough promise to attract the attention of several chemists, who worked out the practical problems of producing a stable form of the substance. Clinical trials of this stable form of penicillin were extremely successful, and by 1945 it was being produced and distributed as an antibiotic on a large scale. That same year, Fleming and two of the chemists, Howard Florey and Ernst Chain, received the Nobel Prize in Medicine for their work on penicillin.

The development of penicillin was one of the most important achievements in modern medicine. Until the introduction of modern antibiotics, the most widespread agents of human death included bacterial infections such as gangrene, tuberculosis, and syphilis. Penicillin proved to be highly effective in curing such infections, and its success led to the creation of the modern pharmaceutical industry. Soon many additional antibiotic compounds were isolated from other fungi or synthesized in the laboratory, leading to a “golden age” of human health.

QA How can modern experiments test hypotheses about the evolutionary impact of ancient environmental changes?

29.1 Fungi Digest Food Outside Their Bodies

Fungi are distinctive in the way they digest their food. They secrete digestive enzymes to break down large food molecules in the environment, then absorb the breakdown products through their cell membranes in a process known as **absorptive heterotrophy**. This mode of nutrition allows them to be successful in a wide variety of environments. Many fungi are **saprobies**, meaning they absorb nutrients from dead organic matter. Others are parasites or predators, feeding on or consuming other living organisms. Still others are mutualists, living in intimate associations with other organisms that benefit both partners.

saprobe [Gk. *sapros*: rotten] An organism (usually a bacterium or fungus) that obtains its carbon and energy by absorbing nutrients from dead organic matter. Also called a saprotroph.

focus your learning

A mycelium, the body of a multicellular fungus, is made up of hyphae.

Mycelia have enormous surface area-to-volume ratios.

Modern fungi evolved from a unicellular protist ancestor that had a flagellum, although most fungi are not motile and have now lost this structure. The probable common ancestor of the animals was also a flagellated protist much like the living choanoflagellates (see [Figure 30.2](#)). Current evidence, including the sequences of many genes, suggests that the fungi, choanoflagellates, and animals share a common ancestor not shared by other eukaryotes. These three lineages form a group known as the **opisthokonts** ([Figure 29.1](#)). A synapomorphy (shared derived trait) of the opisthokonts is a flagellum that, if present, is posterior, as in animal sperm. The flagella of all other eukaryotes attach at the front or sides of the cell, rather than at the rear.

Figure 29.1 Fungi in Evolutionary Context Absorptive heterotrophy and the presence of chitin in their cell walls distinguish the fungi from other opisthokonts.

Synapomorphies that distinguish the fungi as a group among the opisthokonts include absorptive heterotrophy and the presence of **chitin**, a nitrogen-containing structural polysaccharide, in their cell walls. The fungi represent one of the four independent evolutionary origins of large multicellular organisms (plants, brown algae, and animals are the other three).

chitin (kye' tin) [Gk. *kiton*: tunic] The characteristic tough but flexible organic component of the exoskeleton of arthropods, consisting of a complex, nitrogen-containing polysaccharide. Also found in cell walls of fungi.

Yeasts are unicellular, free-living fungi

Most fungi are multicellular, but single-celled species are found in most fungal groups. Unicellular, free-living fungi are referred to as yeasts (**Figure 29.2**). Some fungi have both a yeast life stage and a multicellular life stage. Thus the term “yeast” does not refer to a single taxonomic group, but rather to a lifestyle that has evolved multiple times. Yeasts live in liquid or moist environments and absorb nutrients directly across their cell surfaces.

Figure 29.2 Yeasts Unicellular, free-living fungi are known as yeasts. Many yeasts reproduce by budding — mitosis followed by asymmetrical cell division—as illustrated here.

The ease with which many yeasts can be cultured, combined with their rapid growth rates, has made them ideal ***model organisms** for study in the laboratory. They present many of the same advantages to laboratory investigators as do many bacteria, but because they are eukaryotes, their genome structures and cells are much more like those of humans and other eukaryotes than are those of bacteria.

Multicellular fungi use hyphae to absorb nutrients

The body of a multicellular fungus is called a **mycelium** (plural *mycelia*). A mycelium is composed of a branching mass of individual tubular filaments called **hyphae** (singular *hypha*; **Figure 29.3A**), in which absorption of nutrients takes place primarily at each tip. The cell walls of the hyphae are greatly strengthened by microscopic fibrils of chitin. In some species of fungi, the hyphae are subdivided into cell-like compartments by incomplete cross-walls called **septa**

(singular *septum*). These subdivided hyphae are referred to as **septate**. Septa do not completely close off compartments in the hyphae. Pores at the centers of the septa allow cytoplasm and organelles—sometimes even nuclei—to move in a controlled way between compartments (**Figure 29.3B**). In other species of fungi, the hyphae lack septa but may contain hundreds of nuclei. These multinucleate, undivided hyphae are referred to as coenocytic. The coenocytic condition results from repeated nuclear divisions without cytokinesis.

mycelium (my seel' ee yum) [Gk. *mykes*: fungus] In the fungi, a mass of hyphae.

hypha (high' fuh) (plural: hyphae) [Gk. *hyphe*: web] In the fungi and oomycetes, any single filament.

septate [L. wall] Divided, as by walls or partitions.

(A) Fungal hyphae in dry rot

(B) Anatomy of hyphae

(C) The mycelium of a club fungus

Figure 29.3 Mycelia Are Made Up of Hyphae (A) The minute individual hyphae of fungal mycelia can penetrate small spaces. In this artificially colored micrograph, hyphae (yellow structures) of a dry-rot fungus are penetrating the xylem tissues of a log. (B) The hyphae of septate fungal species are divided into organelle-containing compartments by porous septa. The hyphae of coenocytic fungal species have no septa. (C) The fruiting structure of a club fungus is shortlived, but the filamentous, nutrient-absorbing mycelium can be long-lived and cover large areas.

Certain modified hyphae, called **rhizoids**, anchor some fungi to their substrate (i.e., the dead organism or other matter on which they grow). These rhizoids are not homologous to the rhizoids of plants, and they are not specialized to absorb nutrients and water.

Fungi can grow very rapidly when conditions are favorable. In some species, the total hyphal growth of a fungal mycelium (not the growth of an individual hypha) may exceed 1 kilometer a day! The hyphae may be widely dispersed to forage for nutrients over a large area, or they may clump together in a cottony mass to exploit a rich nutrient source. The familiar mushrooms you may notice growing in moist areas are spore-producing fruiting structures ([Figure 29.3C](#)). In the fungal species that produce these structures, the mycelial mass is often far larger than the visible mushroom. The mycelium of one individual fungus discovered in Oregon covers almost 900 hectares underground and weighs considerably more than a blue whale (the largest animal). Aboveground, this individual is evident only as isolated clumps of mushrooms.

Fungi are in intimate contact with their environment

The filamentous hyphae of a fungus give it a unique relationship with its physical environment. The fungal mycelium has an enormous surface area-to-volume ratio compared with that of most large multicellular organisms. This large ratio allows the fungus to take in a great deal of water and mineral nutrients when soil moisture is high, which allows rapid growth in moist environments. The downside of the large surface area-to-volume ratio of the mycelium is its tendency to lose water rapidly in a dry environment. Thus fungi are most common in moist environments. You have probably observed the tendency of molds, toadstools, and other fungi to appear in damp places.

Another characteristic of some fungi is a tolerance for highly hypertonic environments (those with a solute concentration higher than their own; see [Key Concept 6.3](#)). Many fungi are more resilient than bacteria in hypertonic surroundings. Jelly, for example, does not support bacterial growth because its high sugar content makes it too hypertonic to those organisms, but it may

eventually harbor mold colonies. Mold in the refrigerator illustrates yet another trait of many fungi: tolerance of temperature extremes. Many fungi grow in temperatures as low as -6°C , and some can tolerate temperatures higher than 50°C .

29.1 recap

Fungi, like animals, are opisthokonts. Fungi are distinguished from other opisthokonts by absorptive heterotrophy and by the presence of chitin in their cell walls. Unicellular fungi called yeasts absorb nutrients directly across their cell surfaces. The body form of multicellular fungi—a mycelium made up of rapidly growing hyphae—allows them to practice absorptive heterotrophy efficiently in a variety of moist environments.

learning outcomes

You should be able to:

- Explain how the structure of fungi facilitates their ability to decompose and consume other organisms.
- Make inferences about the presence and abundance of fungi given different environmental features.

-
1. How does fungal structure facilitate absorptive heterotrophy?
 2. What are the advantages and disadvantages to multicellular fungi of the large surface area-to-volume ratio of the mycelium? How does the mycelium restrict the types of environments in which fungi are generally found?

Fungi are important components of healthy ecosystems. They interact with other organisms in many ways, some of which are harmful and some beneficial to those other organisms.

29.2 Fungi Are Decomposers, Parasites, Predators, or Mutualists

Without the fungi, our planet would be very different. Picture Earth with only a few stunted plants and watery environments choked with the remains of dead organisms. Fungi do much of Earth's garbage disposal. Fungi not only help clean up the landscape and form soil, but also play a key role in recycling mineral nutrients. Furthermore, the colonization of the terrestrial environment was made possible in large part by associations that fungi formed with land plants and other organisms.

focus your learning

Were it not for saprobic fungi, Earth's carbon cycle would fail.

A lichen is a complex mutualism between fungi and a photosynthetic microorganism.

Mycorrhizae are mutualistic associations between fungi and the roots of vascular plants.

Saprobic fungi are critical to the planetary carbon cycle

Saprobic fungi, along with bacteria, are the major decomposers on Earth, contributing to the decay of nonliving organic matter and thus to recycling of the elements used by living things. In forests, for example, the mycelia of fungi secrete extracellular enzymes that degrade plant materials into simpler compounds that are then absorbed. Fungi are the principal decomposers of cellulose and lignin, the main components of plant cell walls (most bacteria cannot break down these materials). Other fungi produce enzymes that decompose keratin and thus break down animal structures such as hair and nails.

Were it not for the fungal decomposers, Earth's ***carbon cycle** would fail. Great quantities of carbon atoms would remain trapped forever on forest floors and elsewhere. Instead, those carbon atoms are returned to the atmosphere in the form of CO₂ by fungal respiration, where they are again available for photosynthesis by plants.

There was a time in Earth's history when populations of saprobic fungi declined dramatically. Vast tropical swamps existed during the Carboniferous period, as you saw in [Chapter 24](#). When plants in these swamps died, they began to form peat. Peat formation led to acidification of the swamps. That acidity, in turn, drastically reduced the fungal population. The result? With the decomposers largely absent, large quantities of peat remained on the swamp floor and over time were converted into coal.

In contrast to their decline during the Carboniferous, fungi did very well at the end of the Permian, a quarter of a billion years ago, when the aggregation of continents produced volcanic eruptions that triggered a global mass extinction. The fossil record shows that even as the majority of all multicellular species became extinct, fungi flourished—demonstrating both their hardiness and their role in recycling the elements in dead plants and animals.

Simple sugars and the breakdown products of complex polysaccharides are the favored source of carbon for saprobic fungi. Most fungi obtain nitrogen from proteins or the products of protein breakdown. Many fungi can use nitrate (NO₃⁻) or ammonium (NH₄⁺) ions as their sole source of nitrogen. No known fungus can get its nitrogen directly from inorganic nitrogen gas, however, as can some free-living and plant-associated bacteria (that is, fungi cannot fix nitrogen; see [Key Concept 25.3](#)).

What happens when a fungus faces a dwindling food supply? A common strategy is to reproduce rapidly and abundantly. When conditions are good, fungi produce great quantities of spores, but the rate of spore production is commonly even higher when nutrient supplies go down. The spores may then remain dormant until conditions improve, or they may be dispersed to areas where nutrient supplies are higher.

Not only are fungal spores abundant in number, but they are extremely tiny and easily spread by wind or water ([Figure 29.4](#)). These attributes virtually ensure that the spores will be scattered over great distances and that at least some of them will find conditions suitable for growth. The air we breathe contains as many as 10,000 fungal spores per cubic meter. No wonder we find fungi just about everywhere.

Lycopodium perlatum

Figure 29.4 Spores Galore Puffballs (a type of club fungus) disperse trillions of spores in great bursts. Few of the spores travel very far, however; some 99 percent of them fall within 100 meters of the parent puffball.

 Media Clip 29.1 Fungal Decomposers www.Life11e.com/mc29.1

Some fungi engage in parasitic or predatory interactions

Whereas saprobic fungi obtain their energy, carbon, and nitrogen directly from dead organic

matter, other species of fungi obtain their nutrition from parasitic—and even predatory—interactions.

PARASITIC FUNGI

Mycologists (biologists who study fungi) distinguish between two classes of parasitic fungi based on their degree of dependence on their host. **Facultative parasites** can grow on living organisms but can also grow independently (including on artificial media). **Obligate parasites** can grow only on a specific, living host. The fact that their growth depends on a living host shows that obligate parasites have specialized nutritional requirements.

mycologists Scientists who study fungi.

facultative parasite An organism that can parasitize other living organisms but is also capable of growing independently.

obligate parasites Organisms that can only survive and grow in or on other living organisms, to the detriment of the host.

Plants and insects are the most common hosts of parasitic fungi. The filamentous structure of fungal hyphae is especially well suited to a life of absorbing nutrients from living plants. The slender hyphae of a parasitic fungus can invade a plant through stomata, through wounds, or in some cases, by direct penetration of epidermal cell walls (**Figure 29.5A**). Once inside the plant, the hyphae branch out to expand the mycelium. Some hyphae produce **haustoria**, branching projections that push through cell walls into living plant cells, absorbing the nutrients within those cells. The haustoria do not break through the cell membranes inside the cell walls, but instead invaginate into the membranes, so that the cell membrane fits them like a glove (**Figure 29.5B**). Fruiting structures may form, either within the plant body or on its surface.

(A) Parasitic mildew

Hyphae of fungal mycelium

This hypha is penetrating the leaf's interior through a stoma.

2 μm

(B) The parasitic action of haustoria

Figure 29.5 Invading a Leaf (A) Hyphae of the mildew *Phyllactinia guttata* growing on the surface of a hazel leaf. **(B)** Haustoria are fungal hyphae that push into the living cells of plants, from which they absorb nutrients.

Some parasitic fungi live in a close physical (symbiotic) relationship with a plant host that is usually not lethal to the plant. Others are *pathogenic*, weakening or even killing the host from which they derive nutrition.

Media Clip 29.2 **Mind-Control Killer Fungi** www.Life11e.com/mc29.2

PATHOGENIC FUNGI

Although most human diseases are caused by bacteria or viruses, fungal pathogens are a major cause of death among people with compromised immune systems. Many people with AIDS die of fungal diseases, such as the pneumonia caused by *Pneumocystis jirovecii*. Even *Candida albicans* and certain other yeasts that are normally part of a healthy microbiome can cause severe diseases, such as esophagitis (which impairs swallowing), in individuals with AIDS and in individuals taking immunosuppressive drugs. Various fungi cause other, less threatening human diseases, such as ringworm and athlete's foot. The relatively close relationship between fungi and animals makes it difficult to find drugs that target unique features of fungal metabolism, without harming human patients. As a result, fungal diseases are a growing international health problem.

The worldwide decline of amphibian species has been linked to the spread of a chytrid

fungus, *Batrachochytrium dendrobatidis* (or *Bd* for simplicity). In some areas of the world where this fungus has been present for millennia, amphibian populations appear to be tolerant of *Bd* and it does not cause widespread die-offs. But in other areas, such as western North America and Australia, introductions of *Bd* are implicated in the loss or decline of many frog and salamander populations, or the extinction of entire species. Some strains of *Bd* are native to southern Africa, where they do not appear to cause widespread amphibian declines. Biologists have hypothesized that the spread of *Bd* around the world may have been initiated in the 1930s with exports of the African clawed frog (*Xenopus laevis*), which was once widely used in human pregnancy tests. Recent studies by Erica Rosenblum and her colleagues have shown that Africa may indeed have been one source of the introductions, but that strains of *Bd* appear to have been introduced multiple times from several geographic areas ([Figure 29.6](#)).

Figure 29.6 What is the Origin of Amphibian-Killing Chytrids in North America?

Original Paper: Rosenblum, E. B. et al. 2013. Complex history of the amphibian-killing chytrid fungus revealed with genome resequencing data. *Proceedings of the National Academy of Sciences USA* 110: 9385–9390.

An investigation by Erica Rosenblum and colleagues of *Batrachochytrium dendrobatidis* isolates from around the world suggests that this pathogenic fungus was introduced to western North America several times, from different geographic localities.

HYPOTHESIS Pathogenic forms of *Bd* that kill any amphibians were introduced into western North America from Africa, through importation of African clawed frogs beginning in the 1930s.

METHOD

Collect samples of *Bd* from throughout the world.

Sequence the genomes of the sampled chytrids.

Construct a phylogenetic tree by comparing the DNA sequences of the different samples of *Bd*.

Assess whether or not the resulting tree is consistent with the introduction of *Bd* from Africa to western North America.

RESULTS

CONCLUSION Pathogenic strains of *Bd* appear to have been introduced to western North America from several different sources. At least one strain of *Bd* is consistent with an introduction from Africa, but other strains were more likely introduced from eastern North America or Latin America.

Fungi are by far the most important plant pathogens, causing annual crop losses amounting to billions of dollars. Major fungal diseases of crop plants include black stem rust of wheat and other diseases of wheat, corn, and oats. The agent of black stem rust is *Puccinia graminis*, which has a complicated life cycle that involves two plant hosts (wheat and barberry). In an epidemic in 1935, *P. graminis* was responsible for the loss of about one-fourth of the wheat crop in Canada and the United States.

PREDATORY FUNGI

Some fungi have adaptations that enable them to function as active predators, trapping nearby microscopic protists or animals. This feeding strategy is especially important in environments with lots of available carbon, but little nitrogen, such as wood. The most common predatory strategy seen in fungi is to secrete sticky substances from the hyphae so that passing organisms stick to them. The hyphae then quickly invade the trapped prey, growing and branching within it, spreading through its body, absorbing nutrients, and eventually killing it.

A more dramatic adaptation for predation is the constricting ring formed by some species of soil fungi ([Figure 29.7](#)). When nematodes (tiny roundworms) are present in the soil, these fungi form three-celled rings with a diameter that just fits a nematode. A nematode crawling through one of these rings stimulates the fungus, causing the cells of the ring to swell and trap the worm. Fungal hyphae quickly invade and digest the unlucky victim.

Figure 29.7 Fungus as Predator A nematode is trapped by hyphal rings of the soil-dwelling fungus *Arthrobotrys dactyloides*.

Mutualistic fungi engage in relationships that benefit both partners

Certain relationships between fungi and other organisms have nutritional consequences for both partners. Two relationships of this type are [symbiotic](#) (the partners live in close, permanent contact with each other) as well as **mutualistic** (the relationship benefits both partners).

symbiotic A relationship in which two or more organisms live in close association with one another.

LICHENS A

lichen is not a single organism, but rather a meshwork of at least two radically different species: a fungus and a photosynthetic alga or cyano-bacterium. Recent studies suggest that an additional fungal species (a unicellular yeast) is also usually involved in this mutualism. Together the organisms that constitute a lichen can survive some of the harshest environments on Earth (although they are sensitive to poor air quality; see [Key Concept 29.4](#)). The biota of Antarctica, for example, features more than 100 times as many kinds of lichens as of plants. Relatively little experimental work has focused on lichens, perhaps because they grow so slowly—typically less than 1 centimeter in a year.

lichen (lie' kun) An organism resulting from the symbiotic association of a fungus and either a cyanobacterium or a unicellular alga.

There are nearly 30,000 described “species” of lichens, each of which is assigned the name of its multicellular fungal component. These fungal components may constitute as many as 20 percent of all fungal species. Most of them are sac fungi (Ascomycota). Some of them are able to grow independently without a photosynthetic partner, but most have never been observed in nature other than in a lichen association. The photosynthetic component of a lichen is most often a unicellular green alga, but it can be a cyanobacterium, or may even include both.

Lichens are found in all sorts of exposed habitats: on tree bark, on open soil, and on bare rock. Reindeer moss (not a moss at all, but the lichen *Cladonia subtenuis*) covers vast areas in Arctic, sub-Arctic, and boreal regions, where it is an important part of the diets of reindeer and other large mammals.

The body forms of lichens fall into three principal categories. **Crustose** (crustlike) lichens adhere tightly to their substrate ([Figure 29.8A](#)). **Foliose** (leafy) lichens are loosely attached and grow parallel to their substrate ([Figure 29.8B](#), right). **Fruticose** lichens are highly branched and can grow upward like shrubs, or hang in long strands from tree branches or rocks ([Figure 29.8B](#), left).

crustose A growth form of organisms, such as lichens, in which the organism forms a thin, close, tight bond with the surface of a rock, tree, or other object.

foliose Having a leafy growth form.

fruticose Having a shrubby growth form.

(A) Crustose lichen

(B) Fruticose (left) and foliose (right) lichen

Figure 29.8 Lichen Body Forms The body forms of lichens fall into three principal categories. **(A)** Two crustose lichen species are growing together on this exposed rock surface. **(B)** The light green “shrubby” growth is a fruticose lichen. Foliose lichens have a leafy appearance.

A cross section of a typical foliose lichen reveals a tight upper region of fungal hyphae, a layer of photosynthetic cyanobacteria or algae, a looser hyphal layer, and finally hyphal rhizoids that attach the entire structure to its substrate ([Figure 29.9](#)). The meshwork of fungal hyphae takes up mineral nutrients needed by the photosynthetic cells and also holds water tenaciously, providing a suitably moist environment. The fungus obtains fixed carbon from the photosynthetic products of the algal or cyanobacterial cells.

Figure 29.9 Lichen Anatomy Cross section showing the layers of a foliose lichen and the release of soredia.

Within the lichen, fungal hyphae are tightly pressed against the photosynthetic cells and sometimes invade them without breaching the cell membrane (similar to the haustoria in parasitic fungi; see [Figure 29.5](#)). The photosynthetic cells not only survive these intrusions but continue to grow. Algal cells in a lichen “leak” photosynthetic products at a greater rate than do similar cells growing on their own, and photosynthetic cells taken from lichens grow more rapidly

on their own than when associated with a fungus. On the basis of these observations, we could consider lichen fungi to be parasitic on their photosynthetic partners. In many places where lichens grow, however, the photosynthetic cells could not grow at all on their own.

Lichens can reproduce simply by fragmentation of the vegetative body (the **thallus**) or by means of specialized structures called **soredia** (singular *soredium*). Soredia consist of one or a few photosynthetic cells bound by fungal hyphae. They become detached from the lichen, are dispersed by air currents, and upon arriving at a favorable location, develop into a new lichen thallus (see [Figure 29.9](#)). Alternatively, the fungal partner may go through its sexual reproductive cycle, producing haploid spores. When these spores are discharged, however, they disperse alone, unaccompanied by the photosynthetic partner.

thallus The body of a fungus or plant that is not differentiated into stem and leaves and lacks true roots and a vascular system.

soredia (singular: soredium) Propagules of lichens consisting of one or a few photosynthetic cells bound by fungal hyphae.

Lichens are often the first colonists on new areas of bare rock. They get most of the mineral nutrients they need from the air and rainwater, augmented by minerals absorbed from dust. A lichen begins to grow shortly after a rain, as it begins to dry. As it grows, the lichen acidifies its environment slightly, and this acidity contributes to the slow breakdown of rocks, an early step in soil formation. With further drying, the lichen's photosynthesis ceases. The water content of the lichen may drop to less than 10 percent of its dry weight, at which point it becomes highly insensitive to extremes of temperature.

MYCORRHIZAE

Many vascular plants depend on a symbiotic association with fungi. This ancient association between plants and fungi was critical to the successful exploitation of the terrestrial environment by plants. Unassisted, the root hairs of many plants often do not take up enough water or minerals to sustain growth. However, the roots of such plants usually do become infected with fungi, forming an association called a **mycorrhiza** (plural *mycorrhizae*). There are two types of mycorrhizae, distinguished by whether or not the fungal hyphae penetrate the plant cell walls.

mycorrhiza (my' ko rye' za) (plural: mycorrhizae) [Gk. *mykes*: fungus + *rhiza*: root] An association of the root of a plant with the mycelium of a fungus.

In **ectomycorrhizae**, the fungus wraps around the root tip, and its mass is often as great as that of the root itself ([Figure 29.10A](#)). The fungal hyphae penetrate the root and wrap around individual root cells but do not penetrate the cell walls. An extensive web of hyphae penetrates the soil in the area around the root, so that up to 25 percent of the volume near the root may be fungal hyphae. The hyphae attached to the root increase the surface area for the absorption of water and minerals, and the mass of hyphae in the soil acts like a sponge to hold water in the neighborhood of the root. Infected roots are short, swollen, and club-shaped, and they lack root hairs.

ectomycorrhizae Mutualistic fungi that cover the roots of plants and assist in the uptake of water and minerals from the soil by the plant.

(A) An ectomycorrhizal fungus

Hyphae of the fungus *Pisolithus tinctorius* cover a eucalyptus root.

(B) An arbuscular mycorrhizal fungus

Figure 29.10 Mycorrhizal Associations (A) Ectomycorrhizal fungi wrap themselves around a plant root, increasing the area available for absorption of water and minerals. **(B)** Hyphae of arbuscular mycorrhizal fungi infect the root internally and penetrate the root cell walls, branching within the cells and forming a treelike structure, the arbuscule. (The cell cytoplasm has been removed to better visualize the arbuscule.)

The fungal hyphae of **arbuscular mycorrhizae* enter the root and penetrate the cell walls of the root cells, forming arbuscular (treelike) structures inside the cell wall but outside the cell membrane. These structures, like the haustoria of parasitic fungi and the contact regions of fungal hyphae and photosynthetic cells in lichens, become the primary site of exchange between plant and fungus (**Figure 29.10B**). As in the ectomycorrhizae, the fungus forms a vast web of hyphae leading from the root surface into the surrounding soil.

The mycorrhizal association is important to both partners. The fungus obtains needed organic compounds, such as sugars and amino acids, from the plant. In return, the fungus, because of its very high surface area-to-volume ratio and its ability to penetrate the fine structure of the soil, greatly increases the plant's ability to absorb water and minerals (especially phosphorus). The fungus may also provide the plant with certain growth hormones and may protect it against attack by disease-causing microorganisms.

Plants that have active arbuscular mycorrhizae typically are a deeper green and may resist drought and temperature extremes better than plants of the same species that have little mycorrhizal development. Attempts to introduce some plant species to new areas have failed until some of soil from the native area (presumably containing the fungus necessary to establish mycorrhizae) was provided. Trees without ectomycorrhizae do not grow well in the absence of abundant nutrients and water, so the health of our forests depends on the presence of ectomycorrhizal fungi. Many agricultural crops require inoculation of seeds with appropriate mycorrhizal fungi prior to planting. Without these fungi, the plants are unlikely to grow well, or in some cases at all. Certain plants that live in nitrogen-poor habitats, such as cranberry bushes and orchids, invariably have mycorrhizae. Orchid seeds will not germinate in nature unless they are already infected by the fungus that will form their mycorrhizae. Plants that lack chlorophyll always have mycorrhizae, which they often share with the roots of green, photosynthetic plants. In effect, these plants without chlorophyll are feeding on nearby green plants, using the fungus as a bridge.

Endophytic fungi protect some plants from pathogens, herbivores, and stress

In a tropical rainforest, 10,000 or more fungal spores may land on a single leaf each day. Some are plant pathogens, some do not affect the plant at all, and some invade the plant in a beneficial way. Fungi that live within aboveground parts of plants without causing obvious deleterious symptoms are called **endophytic fungi**. Recent research has shown that endophytic fungi are abundant in plants in all terrestrial environments.

endophytic fungi Fungi that live within the aboveground portions of plants without causing obvious harm to the host plant.

Among the grasses, individual plants with endophytic fungi are more resistant to pathogens and to insect and mammalian herbivores than are plants lacking endophytes. The fungi produce alkaloids (nitrogen-containing compounds) that are toxic to animals. The alkaloids do not harm the host plant. In fact, some plants produce alkaloids (such as nicotine) themselves. The fungal alkaloids also increase the ability of grasses to resist stress of various types, including drought (water shortage) and salty soils. Such resistance is beneficial for some crops, although it can produce toxicity for grazing animals.

The role, if any, of endophytic fungi in most broad-leaved plants is unclear. They may convey

protection against pathogens, or they may simply occupy space within leaves without conferring any benefit, but also without doing harm. The benefit, in fact, might be all for the fungus.

29.2 recap

Fungi interact with other organisms in many ways, both harmful and beneficial. Saprobiic fungi play critical roles in the recycling of elements required by living organisms. Lichens are mutualistic associations of fungi with algae or cyanobacteria. Mycorrhizae are associations of fungi and the roots of plants; they are essential for the survival of most plant species.

learning outcomes

You should be able to:

- Summarize why saprobic fungi are critical to Earth's carbon cycle.
- Summarize the nature and benefits of the lichen association.
- Summarize the nature and benefits of mycorrhizal associations.

1. What is the role of fungi in Earth's carbon cycle?
2. Describe the nature and benefits of the lichen association.
3. How does the mycorrhizal association benefit both the plant and the fungus?

Before molecular techniques clarified the phylogenetic relationships of fungi, one criterion used for assigning fungi to taxonomic groups was the nature of their life cycles — including the types of fruiting structures they produced. The next section will take a closer look at life cycles in the six major groups of fungi.

29.3 Sex in Fungi Involves Multiple Mating Types

Major fungal groups were originally defined by their structures and processes for sexual reproduction and also, to a lesser extent, by other morphological differences. Although fungal life cycles are even more diverse than was once realized, specific types of life cycles generally distinguish the six major groups of fungi: microsporidia, chytrids, zygospor fungi (Zygomycota), arbuscular mycorrhizal fungi (Glomeromycota), sac fungi (Ascomycota), and club fungi (Basidiomycota). [Figure 29.11](#) diagrams the evolutionary relationships of these groups as they are understood today.

Figure 29.11 A Phylogeny of the Fungi Microsporidia are reduced, parasitic fungi whose relationships among the fungi are uncertain. They may be the sister group of most other fungi, or they may be more closely related to particular groups of chytrids or zygospor fungi. The dashed lines indicate that chytrids and zygospor fungi are thought to be paraphyletic; the relationships of the lineages within these two informal groups (see [Table 29.1](#)) are not yet well resolved. The sac fungi and club fungi together form the clade Dikarya.

Activity 29.1 Fungal Phylogeny www.Life11e.com/ac29.1

In most fungi, sexual reproduction involves genetically determined distinctions between two or more mating types.

Microsporidia are parasitic fungi that lack true mitochondria.

Chytrids have flagellated gametes and spores.

Club fungi produce spectacular fruiting structures called basidiomata.

The chytrids and the zygosporangium fungi may not represent monophyletic groups, as they each consist of several distantly related lineages that retain some ancestral features. The clades that are thought to be monophyletic within these two informal groupings are listed in [Table 29.1](#). Recent evidence from DNA analyses has established the placement of the microsporidia among the fungi, the likely paraphyly of the chytrids and the zygosporangium fungi, the independence of arbuscular mycorrhizal fungi from the other fungal groups, and the monophyly of sac fungi and club fungi.

table 29.1 Classification of the Fungi		
Group	Common name	Features
Microsporidia	Microsporidia	Intracellular parasites of animals; greatly reduced, among smallest eukaryotes known; polar tube used to infect hosts
Chytrids (paraphyletic) ^a Chytridiomycota Neocallimastigomycota Blastocladiomycota	Chytrids	Mostly aquatic and microscopic; zoospores and gametes have flagella
Zygomycota (paraphyletic) ^a Entomophthoromycotina Kickxellomycotina Mucoromycotina Zoopagomycotina	Zygosporangium fungi	Reproductive structure is a unicellular zygosporangium with many diploid nuclei; hyphae coenocytic; no fleshy fruiting body
Glomeromycota	Arbuscular mycorrhizal fungi	Form arbuscular mycorrhizae in plant roots; only asexual reproduction is known
Ascomycota	Sac fungi	Sexual reproductive saclike structure known as an ascus, which contains haploid ascospores; hyphae septate; dikaryon
Basidiomycota	Club fungi	Sexual reproductive structure is a basidium, a swollen cell at the tip of a specialized hypha that supports haploid basidiospores; hyphae septate; dikaryon

^a The formally named groups within the chytrids and Zygomycota are each thought to be monophyletic, but their relationships to one another (and to microsporidia) are not yet well resolved.

Fungi reproduce both sexually and asexually

Both asexual and sexual reproduction occur among the fungi ([Figure 29.12](#)). Asexual reproduction takes several forms:

Figure 29.12 A Generalized Fungal Life Cycle Environmental conditions may determine which mode of reproduction—sexual or asexual—takes place at a given time.

The production of (usually) haploid spores within sporangia

The production of haploid spores (not enclosed in sporangia) at the tips of hyphae; in sac fungi, such spores are called **conidia** (Greek *konis*, “dust”)

Cell division by unicellular fungi—either a relatively equal division of one cell into two (*fission*) or an asymmetrical division in which a smaller daughter cell is produced (*budding*)

Simple fragmentation of the mycelium

Sexual reproduction is rare (or even unknown) in some groups of fungi but common in others. Sexual reproduction may not occur in some species, or it may occur so rarely that biologists have never observed it. Species in which no sexual stage has been observed were once placed in a separate taxonomic group because knowledge of the sexual life cycle was considered necessary for classifying fungi. Now, however, these species can be related to other species of fungi through analysis of their DNA sequences.

Sexual reproduction in most fungi features an interesting twist: There is no morphological distinction between female and male structures, or between female and male individuals, in most groups of fungi. Rather, there is a genetically determined distinction between two *or more* mating types. Individuals of the same mating type cannot mate with each other, but they can mate with individuals of another mating type within the same species, thus avoiding selffertilization. Individuals of different mating types differ genetically but are often visually and physiologically indistinguishable.

Microsporidia are highly reduced, parasitic fungi

Microsporidia are unicellular parasitic fungi. They are among the smallest eukaryotes known, with infective spores that are only 1-40 micrometers (µm) in diameter. About 1,500 species have been described, but many more species are thought to exist. Their relationships among the eukaryotes have puzzled biologists for many decades

Microsporidia lack true mitochondria, although they have reduced structures, known as **mitosomes**, that are derived from mitochondria. Unlike mitochondria, however, mitosomes contain no DNA— the mitochondrial genome has been completely transferred to the nucleus. Because microsporidia lack mitochondria, biologists initially suspected that they represented an early lineage of eukaryotes that diverged before the endosymbiotic event from which mitochondria evolved. The presence of mitosomes, however, indicates that this hypothesis is incorrect. DNA sequence analysis, along with the fact that their cell walls contain chitin, has confirmed that the microsporidia are in fact highly reduced, parasitic fungi, although their exact placement among the fungal lineages is still being investigated.

mitosomes Reduced structures derived from mitochondria found in some organisms.

Microsporidia are obligate intracellular parasites of animals, especially of insects, crustaceans, and fish. Some species are known to infect mammals, including humans. Most infections by microsporidia cause chronic disease in the host, with effects that include weight loss, reduced fertility, and a shortened life span. The host cell is penetrated by a polar tube that grows from the microsporidian spore. The function of the polar tube is to inject the contents of the spore, the sporoplasm, into the host (**Figure 29.13**). The sporoplasm then replicates within the host cell and produces new infective spores. The life cycle of some species is complex and involves multiple hosts, whereas other species infect a single host. In some insects, parasitic microsporidia are transmitted vertically (i.e., from parent to offspring). Reproduction is thought to be strictly asexual in some microsporidians, but includes poorly understood asexual and sexual cycles in other species.

Figure 29.13 Invasion of the Microsporidia The spores of microsporidia grow polar tubes that transfer the contents of the spores into the host's cells. The species shown here infects many animals, including humans.

Most chytrids are aquatic

The **chytrids** ([Figure 29.14](#)) include several distinct lineages of mostly aquatic microorganisms once classified with the protists. However, morphological evidence (cell walls that consist primarily of chitin) and molecular evidence support their classification as early-diverging fungi. In this book we use the term “chytrid” to refer to all three of the formally named clades listed as chytrids in [Table 29.1](#), but some mycologists use this term to refer to only one of those clades, the Chytridiomycota. There are fewer than 1,000 described species among the three groups of chytrids.

Chytridiomyces hyalinus

25 μm

Figure 29.14 A Chytrid Branched rhizoids emerge from the sporangium of a mature chytrid.

Chytrids reproduce both sexually and asexually. Like the animals, chytrids that reproduce sexually possess flagellated gametes. The retention of this trait reflects the aquatic environment in which fungi first evolved. Chytrids are the only fungi that include species with flagella at any life cycle stage. Both the spores (called zoospores) and the gametes are flagellated ([Figure 29.15A](#)). There are two types of spores and gametes. Unlike in most fungi, one type of gamete is larger than the other, so the gametes can be distinguished as male (small gametes) and female (large gametes; see [Figure 29.15A](#)). Except for size, however, the two gametes are very similar.

(B) Sexual life cycle of the zygosporic fungi (Zygomycota)

Figure 29.15 Sexual Life Cycles of Chytrids and Zygosporic Fungi (A) Chytrids are the only fungi that possess flagella at any stage of the life cycle. **(B)** The unicellular zygospore, which contains multiple diploid nuclei, is a resting structure unique to the zygosporic fungi.

Q: How is one chytrid gamete identified as male, and the other as female?

The chytrids are diverse in form. Some are unicellular, others have rhizoids, and still others have coenocytic hyphae. They may be parasitic (on organisms such as algae, mosquito larvae, nematodes, and amphibians) or saprobic. Some have complex mutualistic relationships with foregut-fermenting animals such as cattle and deer. Many chytrids live in freshwater habitats or in moist soil, but some are marine.

Some fungal life cycles feature separate fusion of cytoplasm and nuclei

Most members of the remaining four groups of fungi are terrestrial. Although the terrestrial fungi grow in moist places, they do not have motile gametes, so liquid water is not required for fertilization. Instead, the cytoplasm of two individuals of different mating types fuse (a process called **plasmogamy**) before their nuclei fuse (a process called **karyogamy**; see [Figure 29.12](#)). Sexual species of terrestrial fungi include some zygosporic fungi, sac fungi, and club fungi.

plasmogamy The fusion of the cytoplasm of two cells. (Contrast with karyogamy.)

karyogamy The fusion of nuclei of two cells. (Contrast with plasmogamy.)

Zygosporangium reproduce sexually when adjacent hyphae of two different mating types release chemical signals that cause them to grow toward each other. These hyphae produce gametangia, which are specialized cells for reproduction that are retained as part of the hyphae. In the gametangia, nuclei replicate without cell division, resulting in multiple haploid nuclei in both gametangia. The two gametangia then fuse to form a zygosporangium that contains many haploid nuclei of each mating type (**Figure 29.15B**). Haploid nuclei of different mating types then pair up to form multiple diploid nuclei within the zygosporangium. A thick, multilayered cell wall develops around the zygosporangium to form a well-protected resting stage that can remain dormant for months. In harsh environmental conditions, this resting stage may be the only cell that survives as the surrounding cells of the hyphae die. At this stage the single surviving cell is known as a **zygospore**, which is the basis of the name of the zygosporangium. When environmental conditions improve, the nuclei within the zygosporangium undergo meiosis and one or more stalked **sporangiophores** sprout, each bearing a sporangium. Each sporangium contains the products of meiosis: haploid nuclei that are incorporated into spores. These spores disperse and germinate to form a new generation of haploid hyphae.

zygospore Multinucleate, diploid cell that is a resting stage in the life cycle of zygosporangium fungi.

zygospore Multinucleate, diploid cell that is a resting stage in the life cycle of zygosporangium fungi.

sporangiophore A stalked reproductive structure produced by zygosporangium fungi that extends from a hypha and bears one or many sporangia.

(A) Sexual life cycle of the Chytrids

Unlike other fungi, some chytrids produce flagellated male and female gametes from a multicellular haploid stage.

The zygosporangium fungi include four major lineages of terrestrial fungi that live on soil as saprobes, as parasites of insects and spiders, or as mutualists of other fungi and invertebrate animals. They produce no cells with flagella, and only one diploid cell—the zygosporangium—appears in the entire life cycle. Their hyphae are coenocytic. Most species do not form a fleshy fruiting structure. Instead, the hyphae spread in a radial pattern from the spore, with occasional stalked sporangiophores reaching up into the air ([Figure 29.16](#)).

Figure 29.16 Zygosporangium Fungi Produce Sporangioophores These transparent structures are sporangiophores produced by a zygosporangium fungus growing on decomposing animal dung. The sporangiophores grow toward the light and end in tiny sporangia, which the stalked sporangiophores can eject as far as 2 meters. Animals ingest sporangia and then disseminate the spores in their feces.

▶ Animation 29.1 **Life Cycle of a Zygosporangium Fungus** www.Life11e.com/a29.1

More than 1,000 species of zygosporangium fungi have been described. One species you may have seen is *Rhizopus stolonifer*, the black bread mold. *Rhizopus* produces many stalked sporangiophores, each bearing a single sporangium containing hundreds of minute spores (see [Figure 29.15B](#)).

Arbuscular mycorrhizal fungi form symbioses with plants

Arbuscular mycorrhizal fungi (Glomeromycota) are terrestrial fungi that associate with plant roots in a symbiotic, mutualistic relationship (see [Figure 29.10B](#)). Fewer than 200 species have been described, but 80 to 90 percent of all plants have associations with them. Molecular systematic studies have suggested that arbuscular mycorrhizal fungi are the sister group to the Dikarya (sac fungi and club fungi).

The hyphae of arbuscular mycorrhizal fungi are coenocytic. These fungi use glucose from their plant partners as their primary energy source, converting it into other, fungus-specific sugars that cannot return to the plant. Arbuscular mycorrhizal fungi are only known to reproduce asexually.

The dikaryotic condition is a synapomorphy of sac fungi and club fungi

In the two remaining groups of fungi — the sac fungi and the club fungi—some stages have a nuclear configuration other than the familiar haploid or diploid states ([Figure 29.17](#)). In these fungi, karyogamy (fusion of nuclei) occurs long after plasmogamy (fusion of cytoplasm), so that *two genetically different haploid nuclei coexist and divide within each cell of the mycelium*. This stage of the life cycle is called a **dikaryon** (“two nuclei”), and its ploidy is indicated as $n + n$. The dikaryon is a synapomorphy of the sac fungi and club fungi, which are placed together in a clade called **Dikarya**.

(A) Sexual life cycle of the sac fungi (Ascomycota)

Figure 29.17 Sexual Life Cycles among the Dikarya (A) In sac fungi, the products of meiosis are borne in a microscopic sac called an ascus. The fleshy fruiting structure, the ascoma, consists of both dikaryotic and haploid hyphae. (B) The basidium is the characteristic sexual reproductive structure of the club fungi. The fruiting structures, called basidiomata, consist solely of dikaryotic hyphae, and the dikaryotic phase can last a long time.

Q: How does the dikaryotic condition differ from diploidy?

Activity 29.2 Life Cycle of a Dikaryotic Fungus www.Life11e.com/ac29.2

dikaryon (di care' ee ahn) [Gk. *di*: two + *karyon*: kernel] A cell or organism carrying two genetically distinguishable nuclei. Common in fungi.

Eventually, specialized fruiting structures form, within which pairs of genetically dissimilar nuclei—one from each parent—fuse, giving rise to zygotes long after the original “mating.” The diploid zygote nucleus then undergoes meiosis, producing four haploid nuclei. The mitotic descendants of those nuclei become spores, which germinate to give rise to the next haploid generation.

A life cycle with a dikaryotic stage has several unusual features. First, there are no gamete *cells*, only gamete *nuclei*. Second, the only true diploid structure is the zygote, although for a long period the genes of both parents are present in the dikaryon and can be expressed. In effect, the dikaryon is neither diploid ($2n$) nor haploid (n). Rather, it is dikaryotic ($n + n$). Therefore a harmful recessive mutation in one nucleus may be compensated for by a normal allele on the same chromosome in the other nucleus, and dikaryotic hyphae often have characteristics that are different from their n or $2n$ products. The dikaryotic condition is perhaps the most distinctive of the genetic peculiarities of the fungi.

The sexual reproductive structure of sac fungi is the ascus

The **sac fungi** (Ascomycota) are a large and diverse group of fungi found in marine, freshwater, and terrestrial habitats. There are approximately 64,000 known species, nearly half of which are the fungal partners in lichens. The hyphae of sac fungi are segmented by more or less regularly spaced septa. A pore in each septum permits extensive movement of cytoplasm and organelles (including nuclei) from one segment to the next.

Sac fungi are distinguished by the production of sacs called **asci** (singular *ascus*), which at maturity contain sexually produced haploid **ascospores** (see [Figure 29.17A](#)). The ascus is the characteristic sexual reproductive structure of the sac fungi. In the past, the sac fungi were classified on the basis of whether or not the asci are contained within a specialized fruiting structure known as an ascoma (plural *ascomata*) and on differences in the morphology of that fruiting structure. DNA sequence analyses have resulted in a revision of these traditional groupings, however.

ascus (ass' cus) (plural: asci) [Gk. *askos*: bladder] In sac fungi, the club-shaped sporangium within which spores (ascospores) are produced by meiosis.

ascospores Haploid spores contained within the sexual reproductive structure (the ascus) of sac fungi.

SAC FUNGUS YEASTS

Some species of sac fungi are unicellular yeasts. The 1,000 or so species in this group are among the most important domesticated fungi. Perhaps the best known is baker's, or brewer's, yeast (*Saccharomyces cerevisiae*; see [Figure 29.2](#) and [Key Concept 29.4](#)), which metabolizes glucose obtained from its environment into ethanol and carbon dioxide by fermentation. Other sac fungus yeasts live on fruits such as figs and grapes and play an important role in the making of wine. Many others are associated with insects. In the guts of some insects, they provide enzymes that break down materials that are otherwise difficult for the insects to digest, especially cellulose.

Sac fungus yeasts reproduce asexually by budding. Sexual reproduction takes place when two adjacent haploid cells of dissimilar mating types fuse. In some species, the resulting zygote buds to form a diploid cell population. In others, the zygote nucleus undergoes meiosis immediately. When this happens, the entire cell becomes an ascus. Depending on whether the products of meiosis then undergo mitosis, a yeast ascus contains either eight or four ascospores, which germinate to become haploid cells. The sac fungus yeasts have lost the dikaryon stage.

FILAMENTOUS SAC FUNGI

Most sac fungi are filamentous species, such as the cup fungi ([Figure 29.18](#)), in which the ascomata are cup-shaped and can be as large as several centimeters across (although most are much smaller). The inner surfaces of the ascomata, which are covered with a mixture of specialized hyphae and asci, produce huge numbers of spores. The edible ascomata of some

species, including morels and truffles, are regarded by humans as gourmet delicacies (and can sell at prices higher than gold). The underground ascomata of truffles have a strong odor that attracts mammals such as pigs, which then eat the fungi and disperse the spores. Humans sometimes take advantage of pigs' attraction to truffles and use pigs to locate truffles for human consumption.

(A) *Cookeina tricholoma*

(B) *Morchella esculenta*

Figure 29.18 Sac Fungi (A) These brilliant red cups are the ascomata of a cup fungus. **(B)** Morels, which have a spongelike ascoma and a subtle flavor, are considered a culinary delicacy by humans.

The sexual reproductive cycle of filamentous sac fungi includes the formation of a dikaryon, although this stage is relatively brief compared with that in club fungi. Many filamentous sac fungi form multinucleate mating structures (see [Figure 29.17A](#)). Mating structures of two different mating types fuse and produce a dikaryotic mycelium, containing nuclei from both mating types. The dikaryotic mycelium often forms a cup-shaped ascoma, which bears the asci. Only after the formation of asci do the nuclei from the two mating types finally fuse. Both nuclear fusion and the subsequent meiosis that produces haploid ascospores take place within individual asci. The ascospores are ultimately released (sometimes shot off forcefully) by the ascus to begin the new haploid generation.

The sac fungi also include many of the filamentous fungi known as molds. **Molds** consist of filamentous hyphae that do not form large ascomata, although they can still produce asci and ascospores. Many molds are parasites of flowering plants. Chestnut blight and Dutch elm

disease are both caused by molds. The chestnut blight fungus, which was introduced to the United States in the 1890s, had destroyed the American chestnut as a commercial species by 1940. Before the blight, this species accounted for more than half the trees in the eastern North American forests. Another familiar story is that of the American elm. Sometime before 1930, the Dutch elm disease fungus (first discovered in the Netherlands, but native to Asia) was introduced into the United States on infected elm logs from Europe. Spreading rapidly—especially via bark beetles—the fungus destroyed great numbers of American elm trees.

molds Sac fungi composed of filamentous hyphae that do not form large ascomata.

Other plant pathogens among the sac fungi include the powdery mildews that infect cereal crops, lilacs, and roses, among many other plants. Mildews can be a serious problem to farmers and gardeners, and a great deal of research has focused on ways to control these agricultural pests.

The filamentous sac fungi can also reproduce asexually by means of conidia that form at the tips of specialized hyphae ([Figure 29.19](#)). Small chains of conidia are produced by the millions and can survive for weeks in nature. The conidia are often what give molds their characteristic colors.

Figure 29.19 Conidia Chains of conidia (yellow) are developing at the tips of specialized hyphae arising from a *Penicillium notatum* mold. This species is used to produce the antibiotic penicillin.

The basidium is the sexual reproductive structure of club fungi

Club fungi (Basidiomycota) produce some of the most spectacular fruiting structures found among the fungi. These fruiting structures, called [basidiomata](#) (singular *basidioma*), include mushrooms of all kinds, puffballs (see [Figure 29.4](#)), and the bracket fungi often encountered on trees and fallen logs in a damp forest. About 30,000 species of club fungi have been described. They include about 4,000 species of mushrooms, including both poisonous and edible species ([Figure 29.20A](#)). Bracket fungi ([Figure 29.20B](#)) play an important role in the carbon cycle by breaking down wood. They also do great damage to both cut lumber and timber stands. Some

of the most economically damaging plant pathogens are club fungi, including the rust fungi and smut fungi that parasitize cereal grains. In contrast, other club fungi contribute to the survival of plants as fungal partners in ectomycorrhizae.

basidioma (plural: basidiomata) A fruiting structure produced by club fungi.

(A) *Amanita muscaria*

(B) *Laetiporus sulphureus*

Figure 29.20 Club Fungus Basidiomata **(A)** The fly agaric is a poisonous mushroom that contains hallucinogenic compounds. **(B)** A bracket fungus growing parasitically on a tree. Although this particular species is occasionally eaten when young, many similar-appearing bracket fungi are poisonous.

The hyphae of club fungi characteristically have septa with small, distinctive pores. As they grow, haploid hyphae of different mating types meet and fuse, forming dikaryotic hyphae, each cell of which contains two nuclei, one from each parent hypha. The dikaryotic mycelium grows and eventually, when triggered by rain or another environmental cue, produces a basidioma. The dikaryon stage may persist for years, or even centuries. This pattern contrasts with the life cycle of the sac fungi, in which the dikaryon is found only in the stages leading up to formation of the asci.

The **basidium** (plural *basidia*), a swollen cell at the tip of a specialized hypha, is the characteristic sexual reproductive structure of the club fungi (see [Figure 29.17B](#)). In mushroom-forming club fungi, the basidia typically form on specialized structures of the basidiomata known as gills. The basidium is the site of nuclear fusion and meiosis and thus plays the same role in the club fungi as the ascus does in the sac fungi and the zygosporangium does in the zygosporangium fungi.

basidium (bass id' ee yum) In club fungi, the characteristic sporangium in which four **basidiospores** are formed by meiosis and then borne externally before being shed.

After nuclei fuse in the basidium, the resulting diploid nucleus undergoes meiosis, and the four resulting haploid nuclei are incorporated into haploid **basidiospores**, which form on tiny stalks on the outside of the basidium. A single basidioma of the common bracket fungus *Ganoderma applanatum* can produce as many as 4.5 *trillion* basidiospores in one growing season. Basidiospores typically are forcibly discharged from their basidia and then germinate, and give rise to hyphae with haploid nuclei.

29.3 recap

Sexual reproduction is common in some groups of fungi but has never been observed in others. Many fungal species have two or more genetically distinct mating types. The sac fungi and club fungi share a dikaryotic condition, in which two genetically different haploid nuclei coexist in the same cell.

learning outcomes

You should be able to:

- Compare and contrast sexual reproduction in fungi with that of plants and animals.
- Summarize the parasitic life style of microsporidia.
- Infer the likely ancestral habitat of chytrids based on chytrid features.
- Compare and contrast the life cycles of zygosporangium fungi, sac fungi, and club fungi.

1. Explain the concept of mating types. How are they different from male and female sexes?
2. Describe how microsporidia infect the cells of their animal hosts.
3. What feature of the chytrids suggests that the fungi had an aquatic ancestor?
4. What is the role of the zygosporangium in the life cycle of zygosporangium fungi?
5. What distinguishes the fruiting bodies of sac fungi from those of club fungi?

Fungi are of special interest to biologists because of the roles they play in interactions with other organisms, including humans. But they are also useful as tools for studying many kinds of biological problems and for finding solutions to those problems.

29.4 Fungi Have Many Practical Uses

We've briefly noted the important part that fungi play in the production of human foods and beverages. We have also described the diverse roles that fungi play in natural ecosystems, from decomposers to pathogens to mutualistic partners. These diverse ecological roles have led to the use of fungi in studies of environmental change and in remediation of environmental pollution. Many fungi are also important model organisms for laboratory investigations of basic biological process. Others, as you saw at the opening of this chapter, have given us treatments for human diseases.

focus your learning

Baker's yeast, *Saccharomyces cerevisiae*, has many uses in food and drink.

Some *Penicillium* and *Aspergillus* mold species are important in food production.

Many fungi serve directly as a food source.

Lichens are good biological indicators of air quality.

Mycorrhizal fungi are important to reforestation efforts.

Fungi are important in producing food and drink

Grains from grasses provide most of the world's food supply for humans. But in most cases, we do not eat these grains directly as they are produced by the plants. Instead, we use them as a source of starch. To make the starch more pleasing and digestible for human consumption, we usually convert it to more complex and tasty forms of food and drink, often with the help of fungi.

Baker's (or brewer's) yeast (*Saccharomyces cerevisiae*) converts the starch from grain into ethanol. This process also forms carbon dioxide bubbles in bread dough, causing it to rise, which gives baked bread its light texture. The ethanol and carbon dioxide are baked away in bread making (which produces the pleasant aroma of baking bread). In contrast, the ethanol and carbon dioxide are retained when yeast is used to ferment grain into beer. The carbon dioxide gives beer its fizz, and the alcohol and yeast contribute to the taste and appeal of beer to those who enjoy it. Sugars, especially from fruit such as grapes, are also converted into alcohol and carbon dioxide by yeasts in the production of wine (although the carbon dioxide is not retained in most finished wine, as it is in beer). Many different strains of *S. cerevisiae* are used in wine production, which contributes to the distinctive nature of wine from different regions and wineries. Many other species of local, native yeasts are also used in producing distinctive local wines and beers. For example, fission yeast (*Schizosaccharomyces pombe*) was first isolated from African millet beer. Fission yeast takes its specific name (*pombe*) from the Swahili word for beer.

Media Clip 29.3 Time Lapse of Beer Fermentation www.Life11e.com/mc29.3

Brown molds of the genus *Aspergillus* are important in some human diets. *Aspergillus tamarii* acts on soybeans in the production of soy sauce, and *A. oryzae* is used in brewing the Japanese alcoholic beverage sake from rice. *Aspergillus niger* is the source of most commercial citric acid production. Citric acid gives food and soft drinks a tart taste and is also used as a food preservative. But some species of *Aspergillus* that grow on grains and on nuts such as peanuts

and pecans produce extremely carcinogenic (cancer- inducing) compounds called aflatoxins. Aflatoxins can occur in high concentrations in foods such as peanut butter. In the United States and most other industrialized countries, moldy grain infected with *Aspergillus* is typically thrown out. In Africa, where food is scarcer, the grain is often eaten, moldy or not, and causes severe health problems, including high levels of certain cancers.

Penicillium is a genus of green molds, of which some species produce the antibiotic penicillin, as described in the beginning of this chapter. But several species of *Penicillium* are important for food production as well. For example, *P. camembertii* and *P. roqueforti* are the organisms responsible for the characteristic strong flavors of Camembert and Roquefort cheeses, respectively.

Many fungi serve directly as a human food source. Mushroom enthusiasts seek out the delicious fruiting structures of a wide variety of edible sac and club fungi. In the United States, relatively few species of mushrooms are grown commercially, and wild mushrooms are collected mostly for personal consumption. But in many parts of the world, a wide variety of wild mushrooms are collected for sale and consumption. Fungi used for food are not limited to fruiting bodies such as mushrooms, however. Various species of lichens are eaten in Arctic regions as well as in parts of North America and Asia. In southwestern China, for example, several species of lichens are used as a primary ingredient in cooking ([Figure 29.21](#)).

Figure 29.21 Some Lichens Are Edible In southwestern China, several species of lichens that grow on tree bark serve as a primary ingredient in the local cuisine.

Fungi provide important weapons against diseases and pests

We started this chapter with the story of the discovery of penicillin. The discovery of antibiotics produced by fungi revolutionized medical treatment of bacterial diseases in humans and their domestic animals. Live strains of fungi are also used to combat various pest species of plants and animals.

In Africa, the parasitic plant witchweed (*Striga*) causes crop losses of about \$7 billion every year. A group of Canadian biologists discovered that a strain of the mold *Fusarium oxysporum* could be applied to crops to control witchweed without harming the crop plants ([Figure 29.22](#)). Other strains of *Fusarium* that preferentially attack coca plants, the source of cocaine, have been proposed to combat illicit drug production. Still other fungi are used to attack various animal pests, such as termites and aphids, and even malaria-carrying mosquitoes.

Figure 29.22 A Pathogenic Fungus Attacks a Parasitic Plant The fungus *Fusarium oxysporum* is a potent pathogen of witchweed (*Striga*), a parasitic plant that attacks crops. The fungal spores are shown in blue; fungal filaments are in tan. Both colors were added to enhance this scanning electron micrograph.

Lichen diversity and abundance are indicators of air quality

Lichens can live in many harsh environments where few other species can survive, as you saw in [Key Concept 29.2](#). In spite of their hardiness, however, lichens are highly sensitive to air pollution because they are unable to excrete any toxic substances they absorb. This sensitivity means that lichens are good biological indicators of air pollution levels. It also explains why they are not commonly found in heavily industrialized regions or in large cities.

Monitoring the diversity and abundance of lichens growing on trees is a practical and inexpensive system for gauging air quality around cities. Maps of lichen diversity provide environmental biologists with a tool for tracking the distribution of air pollutants and their effects. Sensitive biological indicators of pollution, such as lichen growth, allow biologists to monitor air quality without the use of specialized equipment. Lichens are naturally distributed across the environment, and they can also provide a long-term measure of the effects of air pollution across many seasons and years.

Fungi record and help remediate environmental pollution

Each year, biologists deposit samples of many groups of organisms in the collections of natural history museums. These museum collections serve many purposes, one of which is to document changes in the biota of our planet over time.

Collections of fungi made over many decades or centuries provide a record of the environmental pollutants that were present when the fungi were growing. Biologists can analyze these historical samples to see how different sources of pollutants were affecting our environment before anyone thought to take direct measurements (**Investigating Life: Using Fungi to Study Environmental Contamination**). These long-term records are also useful for analyzing the effectiveness of cleanup efforts and regulatory programs for controlling environmental pollutants.

You have already seen that fungi are critical to the planetary carbon cycle because of their role in breaking down dead organic matter. Fungi are also used in remediation efforts to help clean up sites that have been polluted by oil spills or contaminated with toxic petroleum-derived hydrocarbons. Many herbicides, pesticides, and other synthetic hydrocarbons are broken down primarily through the action of fungi.

Reforestation may depend on mycorrhizal fungi

When a forest is cut down, it is not just the trees that are lost. A forest is an ecosystem that depends on the interaction of many species. As we have discussed, many plants depend on

close relationships with mycorrhizal fungal partners. When trees are removed from a site, the populations of mycorrhizal fungi there decline rapidly. If we wish to restore the forest on the site, we cannot simply replant it with trees and other plants and expect them to survive. The mycorrhizal fungal community must be reestablished as well. For large forest restoration projects, a planned succession of plant growth and soil improvement is often necessary before forest trees can be replanted. As the community of soil fungi gradually recovers, trees that have been inoculated with appropriate mycorrhizal fungi in tree nurseries can be planted to reintroduce greater diversity to the soil fungal community.

Fungi are used as model organisms in laboratory studies

Much of what we know about many basic aspects of cell and molecular biology comes from the study of model organisms. Among the eukaryotes, some fungi have numerous advantages over model plant and animal systems for laboratory investigations.

Of particular importance as model organisms are several species of sac fungi: *Aspergillus nidulans* (a brown mold), *Neurospora crassa* (a red bread mold), *Saccharomyces cerevisiae* (baker's, or brewer's, yeast), and *Schizosaccharomyces pombe* (fission yeast). These species can be cultured in large numbers in small spaces, and they have short generation times, so that genetic investigations can be conducted in days rather than years. Furthermore, their genomes are relatively small and encode relatively few genes compared with those of most plants and animals, so it is easier to elucidate the functions of the fungal genes responsible for basic biological functions.

Using Fungi to Study Environmental Contamination

experiment

Original Paper: Flegal, A. R., C. Gallon, S. Hibdon, Z. E. Kuspa and L. F. Laporte, 2010. Declining—but persistent—atmospheric contamination in central California from the resuspension of historic leaded gasoline emissions as recorded in the lace lichen (*Ramalina menziesii* Taylor) from 1892 to 2006. *Environmental Science and Technology* 44: 5613–5618.

A. Russell Flegal and his colleagues analyzed museum samples of lace lichens (*Ramalina menziesii*) collected between 1892 and 2006 near San Francisco, California. Their goals were to determine the sources of lead contamination and to evaluate the effectiveness of efforts to reduce this contamination.

QUESTION► Is environmental lead contamination through time consistent with known sources of pollution, and have efforts to reduce lead pollution been effective?

METHOD

1. Obtain museum samples of lace lichen (*Ramalina menziesii*) collected near San Francisco.
2. Measure concentrations of lead (Pb) as well as the ratios of two lead isotopes, ^{206}Pb and ^{207}Pb .
3. Compare the ratio of the two isotopes in the lichen samples with that of the possible sources:
 - a. Lead smelter, in operation from 1885 to 1971: $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of 1.15–1.17
 - b. Leaded gasoline, in use from 1930s to the early 1980s: $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of 1.18–1.23
 - c. Resuspension of historic lead contamination as atmospheric aerosols in recent decades: $^{206}\text{Pb}/^{207}\text{Pb}$ ratio of 1.16–1.19

RESULTS

Peak environmental lead contamination occurred in the 1960s to 1980s, with a rapid drop in the early 1980s after the closure of the smelter and the elimination of leaded gasoline. Average $^{206}\text{Pb}/^{207}\text{Pb}$ ratios of lead were below 1.17 before the 1930s, between 1.18 and 1.19 in the 1940s and 1950s, and >1.22 in the early 1980s. The ratios have declined since then.

CONCLUSIONS►

1. The levels of environmental lead contamination, and ratios of lead isotopes, are consistent with the identified sources.
2. The closure of the lead smelter and elimination of leaded gasoline have significantly reduced environmental lead contamination.

work with the data

From the data below, plot lead concentration in the lichen samples against year of sample collection. Make a second plot, this one of $^{206}\text{Pb}/^{207}\text{Pb}$ ratio against year of sample collection.

Sample	Year collected	Lead concentration (μg of Pb/g lichen)	$^{206}\text{Pb}/^{207}\text{Pb}$ ratio
1	1892	11.9	1.165
2	1894	4.0	1.155
3	1906	13.7	1.154
4	1907	22.9	1.157
5	1945	49.9	1.187
6	1957	34.2	1.185
7	1978	50.9	1.221
8	1982	10.0	1.215
9	1983	4.6	1.224
10	1987	1.0	1.198
11	1988	1.3	1.199
12	1995	1.9	1.202
13	2000	0.4	1.184
14	2006	1.8	1.184

QUESTIONS►

1. Calculate trend lines for your plots by plotting the average for the each adjacent pair of observations, from 1894 to 2006. (In other words, plot the average for sample 1 and 2, then the average for sample 2 and 3, and so on, to produce a trend line for the data.)
2. Do your analyses support the conclusions of the study? How do you think you could improve the analysis?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

29.4 recap

Fungi are important to humans in many ways. Some species are consumed directly as food, while others are important in food production. Fungi serve as important indicators of ecosystem health and are critical in reforestation and in pollution remediation efforts. Several species are important model organisms for studies of eukaryote cell and molecular biology. Fungi are widely used to combat diseases and pests.

learning outcomes

You should be able to:

- Describe the ways baker's yeast is used in food and drink.
- Give examples of uses of molds in food products.
- Summarize how fungi can be used for food.
- Assess the advantages of using lichens, over traditional measures, to monitor

environmental conditions.

- Generate plans for land use that take advantage of the importance of mycorrhizal associations.

1. What are some of the ways in which fungi or fungal products contribute to the human food supply?
2. What are some advantages of using surveys of lichen diversity and museum collections of lichens to measure long-term changes in air quality, compared with direct measurements of atmospheric pollutants?
3. Can you develop a strategy for tree harvest that would ease the difficulty and expense of reforestation projects by retaining viable communities of mycorrhizal fungi?
4. Consider the data below for lichens at five survey sites. Predict the relative order of the sites with respect to their distance from the center of a large city. Other factors (besides distance to city center, such as prevailing wind direction) might affect your prediction. Can you think of two other major factors that might influence these results?

Site number	Number of lichen species	Tree branches covered in lichens (%)
1	5	38
2	1	2
3	3	15
4	8	75
5	13	100

investigatinglife

How do fungi affect our daily lives?

Beginning in the 1940s, antibiotics derived from fungi ushered in a “golden age” of freedom from bacterial infections. Today, however, many of these antibiotics are losing their effectiveness as pathogenic bacteria evolve resistance to them ([Figure 29.23](#)).

Figure 29.23 Penicillin Resistance In a petri dish similar to those in Alexander Fleming’s lab, four strains of a pathogenic bacterium have been cultured along with *Penicillium* mold. One strain is resistant to the mold’s antibiotic substance, as is evidenced by its growth up to the mold.

Most medical antibiotics are chemically modified forms of substances that are found naturally in fungi and other organisms. Fungi naturally produce antibiotic compounds to defend themselves against bacterial growth and to reduce competition from bacteria for nutritional resources. These naturally occurring compounds are usually chemically modified to increase their stability, improve their effectiveness, and facilitate synthetic production. From the late 1950s to the late 1990s, no new major classes of antibiotics were discovered. In recent years, however, three new classes of antibiotics have been synthesized based on information learned from naturally occurring, fungally derived antibiotics, leading to improved treatment of some formerly resistant strains of bacteria.

In addition to uses in human health, fungi are critical for production of human food and drink, as well as in agricultural applications. Fungi (especially yeasts) are important model organisms in biological research. Fungi are also sensitive indicators of environmental contamination, and long-term studies of fungi can inform us about changes in levels of environmental toxins over time.

Future directions

Biologists are developing applications to use fungi to combat non-bacterial diseases. One of the more unusual applications of fungi is in the war against malaria. Biologists have discovered that two species of fungi, *Beauveria bassiana* and *Metarhizium anisopliae*, can kill malaria-causing mosquitoes when applied to mosquito netting. Mosquitoes have not yet shown evidence of developing resistance to these biological pathogens.

► 29.1 Fungi Digest Food Outside Their Bodies

- Fungi are distinguished from other **opisthokonts** by **absorptive heterotrophy** and by the presence of chitin in their cell walls. **Review Figure 29.1**
- Some fungi are **saprobies**, others are parasites or predators, and some are mutualists.

saprobe [Gk. *sapros*: rotten] An organism (usually a bacterium or fungus) that obtains its carbon and energy by absorbing nutrients from dead organic matter. Also called a saprotroph.

- Yeasts** are unicellular, free-living fungi.

yeasts Microscopic fungi consisting of single oval cells that reproduce by budding.

- The body of a multicellular fungus is a **mycelium**—a meshwork of filaments called **hyphae**. Hyphae may be **septate** (having septa) or **coenocytic** (multinucleate). **Review Figure 29.3**

mycelium (my seel' ee yum) [Gk. *mykes*: fungus] In the fungi, a mass of hyphae.

hypha (high' fuh) (plural: hyphae) [Gk. *hyphe*: web] In the fungi and oomycetes, any single filament.

septate [L. wall] Divided, as by walls or partitions.

coenocytic (seen' a sit ik) [Gk. *koinos*: common + *kytos*: container] Referring to the condition, found in some fungal hyphae, of “cells” containing many nuclei but enclosed by a single plasma membrane. Results from nuclear division without cytokinesis.

► 29.2 Fungi Are Decomposers, Parasites, Predators, or Mutualists

- Saprobic fungi, which act as decomposers, make crucial contributions to the recycling of elements, especially carbon.
- Many fungi are parasites, harvesting nutrients from host cells by means of **haustoria**. **Review Figure 29.5**
- Certain fungi have relationships with other organisms that are **symbiotic** and **mutualistic**.

symbiotic A relationship in which two or more organisms live in close association with one another.

- Some fungi associate with unicellular green algae, cyanobacteria, or both to form **lichens**, which live on exposed surfaces of rocks, trees, and soil. **Review Figure 29.8**

lichen (lie' kun) An organism resulting from the symbiotic association of a fungus and either a cyanobacterium or a unicellular alga.

- **Mycorrhizae** are mutualistic associations of fungi with plant roots. They improve a plant's ability to take up nutrients and water.

mycorrhiza (my' ko rye' za) (plural: mycorrhizae) [Gk. *mykes*: fungus + *rhiza*: root] An association of the root of a plant with the mycelium of a fungus.

- **Endophytic fungi** live within plants and may provide their hosts with protection from herbivores and pathogens.

endophytic fungi Fungi that live within the aboveground portions of plants without causing obvious harm to the host plant.

► 29.3 Sex in Fungi Involves Multiple Mating Types

- The microsporidia, chytrids, and zygosporic fungi diversified early in fungal evolution. The arbuscular mycorrhizal fungi, sac fungi, and club fungi form a monophyletic group, and the latter two groups form the clade Dikarya. **Review Figure 29.11, Table 29.1, Activity 29.1**
- Many species of fungi reproduce both sexually and asexually. In many fungi, sexual reproduction occurs between individuals of different **mating types**. **Review Figure 29.12**

mating type A particular strain of a species that is incapable of sexual reproduction with another member of the same strain but capable of sexual reproduction with members of other strains of the same species.

- The **microsporidia** are highly reduced unicellular fungi. They are obligate intracellular parasites of animals.
- The three distinct lineages of **chytrids** all include species with flagellated gametes. **Review Figure 29.15A**
- In the sexual reproduction of terrestrial fungi, **plasmogamy** (fusion of cytoplasm) precedes **karyogamy** (fusion of nuclei).

plasmogamy The fusion of the cytoplasm of two cells. (Contrast with karyogamy.)

karyogamy The fusion of nuclei of two cells. (Contrast with plasmogamy.)

- **Zygosporic fungi** have a resting stage known as a zygosporic, which contains many diploid nuclei. Their spores are dispersed from simple stalked **sporangiophores**. **Review Figure 29.15B, Animation 29.1**

zygosporic Multinucleate, diploid cell that is a resting stage in the life cycle of zygosporic fungi.

sporangiophore A stalked reproductive structure produced by zygosporic fungi that extends from a hypha and bears one or many sporangia.

- **Arbuscular mycorrhizal fungi** form symbiotic associations with plant roots. They are only known to reproduce asexually. Their hyphae are coenocytic.
- In sac fungi and club fungi, a mycelium containing two genetically different haploid nuclei, called a **dikaryon**, is formed. The dikaryotic ($n + n$) condition is unique to the fungi.
Review [Figure 29.17](#), **Activity** [29.2](#)

dikaryon (di care' ee ahn) [Gk. *di*: two + *karyon*: kernel] A cell or organism carrying two genetically distinguishable nuclei. Common in fungi.

- **Sac fungi** have septate hyphae with large pores; their sexual reproductive structures are **asci**. Some sac fungi are unicellular yeasts. Many filamentous sac fungi produce fleshy fruiting structures called ascomata. The dikaryon stage in the sac fungus life cycle is relatively brief. **Review** [Figure 29.17A](#)
- **Club fungi** have septate hyphae with distinctive small pores. Their fruiting structures are called basidiomata, and their sexual reproductive structures are basidia. The dikaryon stage may last for years. Review [Figure 29.17B](#)

► 29.4 Fungi Have Many Practical Uses

- Some fungi are consumed as food by humans; other fungi are critical in baking, fermentation, and flavoring food.
- Fungi play important roles in cleaning up environmental pollutants such as synthetic petroleum-derived hydrocarbons.
- The diversity and abundance of lichen growth on trees is a sensitive indicator of air quality.
- Reforestation projects require restoration of the mycorrhizal fungal community.
- Several species of fungi are important model organisms.
- Fungi provide important weapons against diseases and pests.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

9.2 Mycorrhizae are mutualistic associations between fungi and the roots of vascular plants.

Original Paper: Stinson, K. A. et al. 2006. Invasive plant suppresses the growth of native tree seedlings by disrupting belowground mutualisms. *PLoS Biology* 4: e140.

Garlic mustard (*Alliaria petiolata*) is a highly invasive plant of Eurasian origin that causes much damage to native plants where it invades in North America. The manner by which this plant outcompetes native plants is unusual: it secretes chemicals that interfere with the mutualistic relationships the native plants have with arbuscular mycorrhizal fungi.

Some plants are more dependent than others on arbuscular mycorrhizal fungi. Researchers examined the effect of exposure to garlic mustard on several plant species and measured the effect that removal of arbuscular mycorrhizal fungi had on each plant. The figure on p. 634 shows the results of the study. Yellow points, herbaceous colonizers of disturbed forest edges; red points, herbaceous species that live in forest edges and in the gaps between patches of forest; blue points, woody colonizers of forest edges and gaps between patches of forest; green points, tree species of mature forests.

Questions

1. What is the relationship between the effect of exposure to garlic mustard on a plant species and its dependence on arbuscular mycorrhizal fungi? Is this relationship consistent with garlic mustard reducing plant growth by interfering with the plant's fungal mutualists?
2. Which types of plants are most dependent on their mycorrhizal mutualists? Explain your answer. What other observations can be made about habitat and reliance on fungal mutualists?
3. Climate change is expected to lead to greater extremes in temperature and precipitation. What are the likely implications for plants with arbuscular mycorrhizal fungi as climate change becomes more pronounced? Would these aspects of climate change likely increase or decrease the negative effects of exposure to garlic mustard?

A Mysterious Animal Discovered in an Aquarium

In 1883 the zoologist Franz Schulze noticed something unusual in his Austrian laboratory: transparent, flattened organisms were crawling on the sides of his saltwater aquarium. These organisms, which Schulze had collected accidentally along with the sponges that were his primary interest, appeared to be animals, but they were unlike any animals previously described—especially since they continually changed shape as they moved.

Further examination revealed that the new organisms were indeed animals. Structurally, however, they were among the simplest animals that Schulze—or anyone else—had ever observed, being made up of only four types of cells. He named the new species *Trichoplax adhaerens*, which means “sticky hairy plate.” For decades, however, most biologists dismissed Schulze’s findings, insisting that the transparent organisms must be larval forms of other, well-known animals.

In the 1960s more detailed studies confirmed the distinctive nature of *Trichoplax*. Even then, this odd animal continued to be known almost exclusively from aquariums. Finally, in the early 2000s biologists located natural populations of *T. adhaerens* growing on hard surfaces in tropical and subtropical coastal regions. A few additional closely related species have been discovered (although most have not yet been formally named). Collectively, these species are known as placozoans (Greek, “flat animals”).

The more biologists have studied *Trichoplax*, the odder this animal appears. It has the smallest genome of any animal studied to date. The mature stages lack body symmetry and have no mouth, gut, or nervous system. Is *Trichoplax* a relict representative of a group of animals that appeared early in animal evolution?

Which groups of organisms are at the root of the animal tree has been a subject of considerable investigation and debate. Several possible hypotheses of relationships have been explored with genomic analyses. The structural simplicity of *Trichoplax* is now considered by most biologists to be an evolutionary reversal from a more complex body form. Most genomic studies point to other groups of animals as forming the earliest split with the remaining species.

This chapter explores the earliest branches on the animal tree and shows how a few fundamental “body plans” have been modified to yield the remarkable variety of animal forms described in this and the following two chapters.

QA Which animal groups are involved in the earliest split in the animal tree?

30.1 Some Animal Characteristics Evolved More Than Once

How do we recognize an organism as an animal? That may seem obvious for many familiar animals, but less so for groups such as sponges, which were once thought to be plants.

focus your learning

Most animals are multicellular heterotrophs with internal digestion, muscular systems that allow movement, and nervous systems, although none of these features is completely diagnostic for all animals.

A few microstructural features and genome sequences provide the best evidence of animal monophyly.

Several patterns of embryonic cleavage exist among animals.

Distinct layers of cells form during the early development of most animals.

Bilaterians, named for their pattern of symmetry, include protostomes and deuterostomes.

Some of the general characteristics we associate with animals include:

Multicellularity. In contrast to the bacteria, archaea, and most protists (see [Chapters 25](#) and [26](#)), all animals are multicellular. Animal life cycles feature complex patterns of development from a single-celled zygote into a multicellular adult.

Heterotrophic metabolism. In contrast to most plants, all animals are heterotrophs. Animals are able to synthesize very few organic molecules from inorganic chemicals, so they must obtain the necessary organic molecules from their environment.

Internal digestion. Although the fungi are also heterotrophs (see [Chapter 29](#)), animals and fungi digest their food differently. While fungi digest food outside their bodies, most animals use internal processes to break down materials from their environment into the organic molecules they need. Most animals ingest food into an internal **gut** that is continuous with the outside environment and in which digestion takes place.

gut An animal's digestive tract.

Movement and nervous systems. In contrast to the majority of plants and fungi, most animals can move their bodies. This movement is often coordinated through a well-developed nervous system, which also typically functions as a sensory system. Animals must move to find food or bring food to them. Muscle tissue and nervous systems are unique to animals, and many animal body plans are specialized for movement and detection of prey.

Although these general features help us recognize animals, none is diagnostic for all animals. Some animals do not move, at least during certain life stages, and some plants and fungi do have limited movement. Some animals lack a nervous system, and the diffuse nerve nets (which lack a coordinating brain) of ctenophores and cnidarians are distinct and independently evolved from the [central nervous systems](#) of bilaterians. Some animals lack a gut, and many

multicellular organisms are not animals. So on what basis do we group all animals together in a single clade?

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

Animal monophyly is supported by gene sequences and morphology

The most convincing evidence that all the organisms considered to be animals share a common ancestor comes from phylogenetic analyses of their gene sequences. Relatively few complete animal genomes are available, but more are being sequenced each year. Analyses of these genomes, as well as of many individual gene sequences, have shown that the animals are indeed monophyletic. The best-supported phylogenetic tree for the major animal groups is shown in [Figure 30.1](#) [Table 30.1](#) summarizes the living members of those groups.

Figure 30.1 A Phylogenetic Tree of the Animals This tree presents the best-supported current hypotheses of the evolutionary relationships among major groups of animals. The traits highlighted by red circles will be explained in this and the following two chapters.

Q: Based on this tree, which of the depicted traits evolved multiple times among animals, and in which lineages?

table 30.1 Summary of Living Members of the Major Animal Groups

Group	Approximate number of living species	Major subgroups, other names,
-------	--------------------------------------	-------------------------------

described		and notes
Ctenophores	250	Comb jellies
Sponges	8,500	Demosponges, glass sponges, calcareous sponges
Placozoans	2	Additional species have been discovered but not yet formally named
Cnidarians	12,500	Anthozoans: Corals, sea anemones Hydrozoans: Hydras and hydroids Scyphozoans: Jellyfish Myxozoans: Parasitic mucous animals; sometimes placed in group distinct from cnidarians
Orthonectids	45	Microscopic wormlike parasites of marine invertebrates; relationships uncertain
Rhombozoans	125	Tiny (0.5–7 mm) parasites of cephalopods; relationships uncertain
PROTOSTOMES		
Arrow worms	180	Glass worms
Lophotrochozoans		
Bryozoans	5,500	Moss animals
Entoprocts	170	Sessile aquatic animals, 0.1–7 mm long, superficially similar to bryozoans
Flatworms	30,000	Free-living flatworms; flukes and tapeworms (all parasitic); monogeneans (ectoparasites of fish)
Gastrotrichs	800	“Hairy backs”
Rotifers and relatives	3,000	Rotifers, spiny-headed worms, and jaw worms
Ribbon worms	1,200	Proboscis worms
Phoronids	10	Sessile marine filter feeders
Brachiopods	450	Lampshells
Annelids	19,000	Polychaetes (generally marine; may not be monophyletic) Clitellates: earthworms, freshwater worms, leeches
Mollusks	117,000	Monoplacophorans Chitons Bivalves: Clams, oysters, mussels Gastropods: Snails, slugs, limpets Cephalopods: Squid, octopuses, nautiloids
Ecdysozoans		
Kinorhynchs	180	Mud dragons
Loriciferans	30	Brush heads
Priapulids	20	Penis worms
Nematodes	25,000	Roundworms
Horsehair worms	350	Gordian worms
Onychophorans	180	Velvet worms
Tardigrades	1,200	Water bears
Arthropods		
Chelicerates	114,000	Horseshoe crabs, pycnogonids, and arachnids (scorpions, harvestmen, spiders, mites, ticks)

Myriapods	12,000	Millipedes, centipedes
Crustaceans	67,000	Crabs, shrimps, lobsters and crayfish, barnacles, copepods
Hexapods	1,020,000	Insects and their wingless relatives
DEUTEROSTOMES		
Xenoturbellids	5	Secondarily simple marine worms; relationships uncertain
Acoels	400	Very small (mostly <2 mm) flattened marine worms; relationships uncertain
Echinoderms	7,500	Crinoids (sea lilies and feather stars), brittle stars, sea stars, sea daisies, sea urchins, sea cucumbers
Hemichordates	120	Acorn worms and pterobranchs
Tunicates	2,800	Sea squirts (ascidians), salps, and larvaceans
Lancelets	35	Cephalochordates
Vertebrates	65,000	Hagfish, lampreys, cartilaginous fish, ray-finned fish, coelacanths, lungfish, amphibians, reptiles (including birds), and mammals

Although animals were considered to belong to a single clade long before gene sequencing became possible, surprisingly few morphological features are shared across all species of animals. Two morphological synapomorphies have been identified that distinguish the animals:

- . A common set of extracellular matrix molecules, including collagen and proteoglycans (see [Figure 5.22](#))
- . Unique types of junctions between cells (tight junctions, desmosomes, and gap junctions; see [Figure 6.7](#))

Although some animals in a few groups lack one or the other of these traits, it is believed that these traits were possessed by the ancestor of all animals and subsequently lost in those groups. Similarities among animals in the organization and function of Hox and other developmental genes (see [Chapter 19](#)) provide additional evidence of developmental mechanisms shared by a common animal ancestor.

The common ancestor of animals was likely a colonial flagellated protist similar to existing colonial choanoflagellates. Choanoflagellate colonies have clearly retained similarities to the multicellular sponges ([Figure 30.2](#)). Why did early animals begin to form multicellular colonies? One hypothesis is that multicellular colonies are more efficient than single cells are at capturing their prey. Experiments with living species of choanoflagellates show that they spontaneously form multicellular colonies in response to signaling compounds that are found on certain species of planktonic bacteria they eat ([Figure 30.3](#)).

(A) Colony of choanoflagellate protists

(B) Structure and function of sponge choanocytes

Figure 30.2 Choanocytes in Sponges Resemble Choanoflagellate Protists (A)

The similarity of choanoflagellate protist colonies to sponge choanocytes supports an evolutionary link between this protist lineage and the animals. **(B)** A sponge moves food-containing water through its body by beating the flagella of its choanocytes. Water enters the sponge through small pores and passes into water canals or an open atrium, where the choanocytes capture food particles from the water. The spicules are supportive, skeletal structures.

Figure 30.3 What Induces Choanoflagellates to Form Multicellular Colonies?

Original Paper: Alegado, R. A. et al. 2012. A bacterial sulfonolipid triggers multicellular development in the closest living relatives of animals. *eLife* 1: e00013.

The choanoflagellate *Salpingoeca rosetta* forms multicellular, rose-shaped colonies (rosettes) at low frequencies in natural conditions. The rosette colonies are more efficient than are single cells at capturing some prey species of planktonic bacteria. Rosanna Alegado and her collaborators investigated the chemical signals that induce the choanoflagellates to form multicellular colonies when environmental conditions favor the rosette formations.

HYPOTHESIS ▶ Multicellular colonies of *S. rosetta* are induced by chemical compounds found on specific species of planktonic bacteria.

METHOD

1. Isolate individual species of bacteria from an environmental sample of *S. rosetta* and its associated bacterial community.
2. Use a combination of antibiotics to produce a bacteria-reduced culture line of *S. rosetta* that does not spontaneously form rosette colonies (the RCA line, for “rosette colonies absent”).
3. Feed the RCA line with each of the isolated species of bacteria from Step 1. Record any rosette colony formation.
4. Isolate compounds that induce multicellular colony formation from rosette-producing bacteria identified in Step 3.

RESULTS

Alegado and colleagues tested various compounds from planktonic bacteria in the genus *Algoriphagus* and found that RIF-1, a sulfonolipid produced by the bacteria, is the signal that induces formation of multicellular colonies in *S. rosetta*.

CONCLUSION ▶ A chemical signal (RIF-1) from a particular genus of prey bacteria can induce the formation of multicellular colonies in some species of choanoflagellates.

One hypothesis of animal origins postulates a choanoflagellate-like lineage in which certain cells in the colony became specialized—some for movement, others for nutrition, others for reproduction, and so on. Once this functional specialization had begun, cells could have

continued to differentiate. Coordination among groups of cells could have improved by means of specific regulatory and signaling molecules that guided differentiation and migration of cells in developing embryos. Such coordinated groups of cells eventually could have evolved into the larger and more complex organisms that we call animals.

Nearly 80 percent of the 1.8 million named species of living organisms are animals, and millions of additional animal species await discovery (see [Chapter 31](#) opening story). Evidence for the evolutionary relationships among animal groups can be found in fossils, in patterns of embryonic development, in the morphology and physiology of living animals, in the structure of animal proteins, and in gene sequences. Increasingly, studies of the phylogenetic relationships among major animal groups have come to depend on genomic sequence comparisons.

A few basic developmental patterns differentiate major animal groups

Differences in patterns of embryonic development have until recently provided many of the important clues to animal phylogeny. Analyses of gene sequences, however, are now showing that some developmental patterns are more evolutionarily variable than previously thought. Here we describe the basic developmental patterns that vary among the major animal clades.

The early cell divisions of an embryo are known as ***cleavage**. Several different patterns of cleavage exist among animals. Although these patterns can be useful for characterizing major animal groups, genomic analyses have shown that many changes have occurred in cleavage patterns throughout animal evolution.

Cleavage patterns are influenced by the configuration of the yolk, the acellular nutritive material that nourishes the growing embryo. The eggs of many animal groups contain a small amount of yolk that is evenly distributed throughout the egg cytoplasm. In some of these groups, the zygote and its descendant cells divide completely and evenly in a pattern known as **radial cleavage**. Radial cleavage is thought to be the ancestral condition for the bilaterian animals, as it is widely distributed among the major lineages. **Spiral cleavage**—a complicated permutation of radial cleavage—is found among many lophotrochozoans (a group that includes earthworms and clams). Lophotrochozoans with spiral cleavage are thus sometimes known as spiralian. The early branches of the ecdysozoans (molting animals, such as insects and nematodes) have radial cleavage, but most ecdysozoans have an idiosyncratic cleavage pattern that is neither radial nor spiral in organization (see [Figure 43.3C](#)). In reptiles, the presence of a large body of yolk within the fertilized egg creates an incomplete cleavage pattern in which the dividing cells form an embryo on top of the yolk mass.

radial cleavage Embryonic development in which the planes of cell division are parallel and perpendicular to the animal-vegetal axis of the embryo. (Compare to spiral cleavage.)

spiral cleavage A form of complete cleavage in which the cleavage planes are at oblique angles to the animal-vegetal axis.

Distinct layers of cells form during the early development of most animals. These cell layers differentiate into specific organs and organ systems as development continues. The embryos of **diploblastic** animals have two cell layers: an outer **ectoderm** and an inner **endoderm**. Embryos of **triploblastic** animals have, in addition to ectoderm and endoderm, a third distinct cell layer, **mesoderm**, which lies between the ectoderm and the endoderm (see [Figure 43.6](#)). The existence of three cell layers in embryos is a synapomorphy of the triploblastic animals (which form a clade), whereas the diploblastic animals (ctenophores, placozoans, and cnidarians, which are not a clade) exhibit the ancestral condition (see [Figure 30.1](#)). Some biologists also consider sponges to be diploblastic, but since they do not have clearly differentiated tissue types or embryonic cell layers, they are usually considered to be **monoblastic**.

diploblastic Having a body derived from only two embryonic cell layers (ectoderm and endoderm, but no mesoderm) (Contrast with monoblastic, triploblastic.)

ectoderm [Gk. *ektos*: outside + *derma*: skin] The outermost of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skin, sense organs, and nervous system.

endoderm [Gk. *endo*: within + *derma*: skin] The innermost of the three embryonic germ layers delineated during gastrulation. Gives rise to the digestive and respiratory tracts and structures associated with them.

triploblastic Having a body derived from three embryonic cell layers (ectoderm, mesoderm, and endoderm). (Contrast with diploblastic, monoblastic.)

mesoderm [Gk. *mesos*: middle + *derma*: skin] The middle of the three embryonic germ layers first delineated during gastrulation. Gives rise to the skeleton, circulatory system, muscles, excretory system, and most of the reproductive system.

monoblastic Having a body derived from a single embryonic cell layer. (Contrast with diploblastic, triploblastic.)

During early development in many animals, in a process known as gastrulation, a hollow ball one cell thick indents to form a cup-shaped structure. The opening of the cavity formed by this indentation is called the blastopore ([Figure 30.4](#)). The process of gastrulation is detailed in [Key Concept 43.3](#); the point to remember here is that the *overall pattern* of gastrulation immediately after formation of the blastopore divides the triploblastic animals into two major groups:

Figure 30.4 Gastrulation Illuminates Evolutionary Relationships The blastopore is clear in this scanning electron micrograph of a sea urchin gastrula. Because sea urchins (echinoderms) are deuterostomes, this blastopore will eventually become the anal end of the animal's gut.

- In the **protostomes** (Greek, “mouth first”), the mouth arises from the blastopore, and the anus forms later.?

- . In the **deuterostomes** (“mouth second”), the blastopore becomes the anus, and the mouth forms later.

Although the developmental patterns of animals are more varied than suggested by this simple dichotomy, sequencing data indicate that the protostomes and deuterostomes represent distinct animal clades. Together these two groups are known as the bilaterians (named for their usual bilateral symmetry), and they account for the vast majority of animal species.

30.1 recap

We generally recognize animals as multicellular heterotrophs with internal digestion, muscular systems that allow movement, and nervous systems. Animals are thought to be monophyletic because they share several derived traits, especially among their gene sequences. Major developmental differences also provide evidence of their evolutionary relationships.

learning outcomes

You should be able to:

- Explain the ways that animals differ from each of the other major groups.
- Contrast the major morphological and developmental features that distinguish major groups of animals.

1. What general features distinguish animals from other major groups of living organisms?
2. Differentiate among the members of each of the following sets of related terms:
 - a. radial symmetry/bilateral symmetry
 - b. protostome/deuterostome
 - c. diploblastic/triploblastic

We will begin our exploration of animal diversity by discussing the general features of animal body plans. Later in this chapter we will describe several groups of animals that diverged before the origin of the bilaterians. We will devote [Chapter 31](#) to the protostomes and [Chapter 32](#) to the deuterostomes.

30.2 Animals Diverged with Distinct Body Plans

The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts are referred to as its **body plan**. As [Chapter 19](#) described, the regulatory and signaling genes that govern the development of body symmetry, body cavities, segmentation, and appendages are widely shared among the different animal groups. Thus we might expect animals to share body plans.

body plan The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts.

focus your learning

Bilateral symmetry is strongly associated with cephalization.

The body plans of triploblastic animals can be divided into three types based on the presence and structure of an internal body cavity.

Segmentation facilitates specialization of different body regions.

Appendages that project from the body greatly enhance an animal's ability to move around.

Nervous systems are important for sensing the environment, processing information, and coordinating movement.

Although animal body plans vary tremendously, they can be seen as variations on five key features:

- . The *symmetry* of the body
- . The structure of the *body cavity*
- . The *segmentation* of the body
- . *External appendages* that are used for sensing, chewing, locomotion, mating, and other functions
- . The development of the *nervous system*

Each of these features affects how an animal moves and interacts with its environment.

Most animals are symmetrical

The overall shape of an animal can be described by its **symmetry**. An animal is said to be symmetrical if it can be divided along at least one plane into similar halves. Animals that have no plane of symmetry are said to be asymmetrical. Placozoans and many sponges are asymmetrical, but most other animals have some kind of symmetry, which is governed by the expression of regulatory genes during development.

symmetry Pertaining to an attribute of an animal body in which at least one plane can divide

the body into similar, mirror-image halves. (See bilateral symmetry, radial symmetry.)

The simplest form of symmetry is **spherical symmetry**, in which body parts radiate out from a central point. An infinite number of planes passing through the central point can divide a spherically symmetrical organism into similar halves. Spherical symmetry is widespread among unicellular protists, but most animals possess other forms of symmetry.

spherical symmetry The simplest form of symmetry, in which body parts radiate out from a central point such that an infinite number of planes passing through that central point can divide the organism into similar halves.

In organisms with **radial symmetry**, body parts are arranged around one main axis at the body's center (**Figure 30.5A**). Ctenophores (comb jellies) are radially symmetrical, as are many cnidarians (such as sea anemones and jellyfish) and echinoderms. A perfectly radially symmetrical animal can be divided into similar halves by any plane that contains the main axis. However, most radially symmetrical animals—including the adults of echinoderms such as sea stars—are slightly modified, so that only some planes can divide them into identical halves. Some radially symmetrical animals are sessile (they remain fixed in one place) or drift with water currents. Others move about slowly but can move equally well in any direction.

radial symmetry The condition in which any two halves of a body are mirror images of each other, providing the cut passes through the center; a cylinder cut lengthwise down its center displays this form of symmetry.

(A) Radial symmetry

(B) Bilateral symmetry

Figure 30.5 Body Symmetry Most animals are either (A) radially or (B) bilaterally symmetrical.

Bilateral symmetry is characteristic of animals that have a distinct front end, which typically precedes the rest of the body as the animal moves. A bilaterally symmetrical animal can be divided into mirror-image (left and right) halves by a single plane that passes through the midline of its body. This plane runs from the front, or **anterior**, end of the body, to the rear, or **posterior**, end (**Figure 30.5B**). A plane at right angles to the midline divides the body into two dissimilar sides. The back of a bilaterally symmetrical animal is its **dorsal** surface; the underside is its **ventral** surface.

bilateral symmetry The condition in which only the right and left sides of an organism, divided by a single plane through the midline, are mirror images of each other.

anterior Toward or pertaining to the tip or headward region of the body axis. (Contrast with posterior.)

posterior Toward or pertaining to the rear. (Contrast with anterior.)

dorsal [L. *dorsum*: back] Toward or pertaining to the back or upper surface. (Contrast with ventral.)

ventral [L. *venter*: belly, womb] Toward or pertaining to the belly or lower side. (Contrast with dorsal.)

Bilateral symmetry is strongly correlated with **cephalization** (Greek *kephalos*, “head”), which is the concentration of sensory organs and nervous tissues at the anterior end of the animal. Cephalization has been favored by natural selection because the anterior end of a bilaterally symmetrical animal typically encounters new environments first.

cephalization (sef ah luh zay’ shun) [Gk. *kephale*: head] The evolutionary trend toward increasing concentration of brain and sensory organs at the anterior end of the animal.

The structure of the body cavity influences movement

The body plans of triploblastic animals can be divided into three types based on the presence and structure of an internal, fluid-filled **body cavity**.

body cavity An internal, fluid-filled space, enclosed by mesoderm in triploblastic animals.

Acoelomate animals such as flatworms lack an enclosed, fluid-filled body cavity. Instead, the space between the gut (derived from endoderm) and the muscular body wall (derived from mesoderm) is filled with masses of cells called **mesenchyme** (Figure 30.6A). These animals typically move by beating cilia.

acoelomate An animal that does not have a coelom.

mesenchyme (mez' en kyme) [Gk. *mesos*: middle + *enchyma*: infusion] Embryonic or unspecialized cells derived from the mesoderm.

(A) Acoelomate (flatworm)

(B) Pseudocoelomate (roundworm)

(C) Coelomate (earthworm)

Figure 30.6 Animal Body Cavities (A) Acoelomates do not have enclosed body cavities. (B) Pseudocoelomates have a body cavity enclosed by mesoderm only on its outside. (C) Coelomates have a body cavity that is enclosed by mesoderm on both its inside and its outside.

- **Pseudocoelomate** animals have a body cavity called a pseudocoel, a fluid-filled space lying between the mesoderm and endoderm. Many of the internal organs are suspended in the pseudocoel, which is enclosed by muscles (mesoderm) only on its outside; there is no inner layer of mesoderm surrounding the internal organs ([Figure 30.6B](#)).

pseudocoelomate (soo' do see' low mate) [Gk. *pseudes*: false + *koiloma*: cavity]
Having a body cavity, called a pseudocoel, consisting of a fluid-filled space in which many of the internal organs are suspended, but which is enclosed by mesoderm only on its outside.

- **Coelomate** animals have a body cavity, the coelom, that develops within the mesoderm. The coelom is lined with a thin layer of tissue called the **peritoneum**, which also surrounds the internal organs. The coelom is thus completely enclosed by mesoderm ([Figure 30.6C](#)).

coelomate Possessing a coelom.

peritoneum The mesodermal lining of the body cavity in coelomate animals.

 Activity 30.1 Animal Body Cavities www.Life11e.com/ac30.1

The structure of an animal's body cavity strongly influences the ways in which it can move. The body cavities of many animals function as **hydrostatic skeletons**. Fluids are relatively incompressible, so when the muscles surrounding a fluid-filled body cavity contract, fluids shift to another part of the cavity. If the body tissues around the cavity are flexible, fluids squeezed out of one region can cause some other region to expand. The moving fluids can thus move specific body parts. (You can see how a hydrostatic skeleton works by watching a snail emerge from its shell.) A coelomate animal has better control over the movement of the fluids in its body cavity than a pseudocoelomate animal does. An animal that has longitudinal muscles (running along the length of the body) as well as circular muscles (encircling the body cavity) has even greater control over its movement.

hydrostatic skeleton A fluid-filled body cavity that transfers forces from one part of the body to another when acted on by surrounding muscles.

In terrestrial environments, the hydrostatic function of fluid-filled body cavities applies mostly to relatively small, soft-bodied organisms. Most larger animals (as well as many smaller ones) have hard skeletons that provide protection and facilitate movement. Muscles are attached to those firm structures, which may be inside the animal or on its outer surface (in the form of a shell or cuticle).

Segmentation improves control of movement

Segmentation—the division of the body into segments—is seen in many animal groups. Segmentation facilitates specialization of different body regions. It also allows an animal to alter the shape of its body in complex ways and to control its movements precisely. If an animal's body is segmented, muscles in each individual segment can change the shape of that segment independently of the others. In only a few segmented animals is the body cavity separated into discrete compartments, but even partly separated compartments allow better control of movement. As we will see in [Chapters 31](#) and [32](#), segmentation occurs in several groups of protostomes and deuterostomes.

segmentation Division of an animal body into segments.

In many animals, such as annelids (earthworms and their relatives), similar body segments are repeated many times ([Figure 30.7A](#)). In other animals, including most arthropods, segments differ strikingly from one another ([Figure 30.7B](#)). As we'll describe in [Chapter 31](#), the dramatic evolutionary radiation of the arthropods (including the insects, spiders, centipedes, and crustaceans) was based on modifications of a segmented body plan that features muscles attached to the inner surface of an external skeleton, including a variety of external appendages that move these animals. In some animals, distinct body segments are not apparent externally (as with the segmented vertebrae of vertebrates, including humans). Nonetheless, muscular segmentation is clearly visible in humans with well-defined, muscular bodies ([Figure 30.7C](#)).

(A) *Hermodice carunculata*

Tail segments are modified for hunting and defense.

Abdominal segments are modified for digestion and reproduction.

Anterior segments have fused and bear appendages for locomotion and feeding.

(B) *Hadrurus arizonensis*

(C) *Homo sapiens*

Figure 30.7 Segmentation (A) All of the segments of this marine fireworm, an annelid, are similar. Its appendages are tipped with bristles (setae) that are used for locomotion and (in this species) for protection—the setae contain a noxious toxin. **(B)** Segmentation allows the evolution of differentiation among the segments. The segments of this scorpion, an arthropod, differ in their form, their function, and the appendages they bear. **(C)** Muscular segmentation is clearly visible in the abdomen of this body builder.

Appendages have many uses

Getting around under their own power is important to many animals. It allows them to obtain food, avoid predators, and find mates. Even some species that are sessile as adults, such as sea anemones, have larval stages that use cilia to swim, thus increasing the animal's chances of finding a suitable habitat.

Appendages that project from the body greatly enhance an animal's ability to move around. Many echinoderms, including sea urchins and sea stars, have myriad tube feet that allow them to move slowly across the substrate (see [Figure 32.3B](#)). Animals whose appendages have become modified into specialized limbs are capable of better controlled, more rapid movement. The presence of jointed limbs has been a prominent factor in the evolutionary success of the arthropods and the vertebrates. In four independent instances—among the arthropod insects and among the vertebrate pterosaurs, birds, and bats—body plans emerged in which limbs were modified into wings, allowing these animals to use powered flight (see [Figure 19.15](#)).

Appendages also include many structures that are not used for locomotion. Many animals have antennae, which are specialized appendages used for sensing the environment. Other appendages (such as the claws and mouthparts of many arthropods) are adaptations for capturing prey or chewing food. In some species, appendages are used for reproductive purposes, such as sperm transfer or egg incubation.

Nervous systems coordinate movement and allow sensory processing

The bilaterian animals have a well-coordinated central nervous system. More diffuse nervous systems, called [nerve nets](#), are present in some other animals, such as ctenophores and cnidarians. Nervous systems appear to be completely absent in a few groups, such as sponges and placozoans.

nerve nets Diffuse, loosely connected aggregations of nervous tissues in certain non-bilaterian animals such as cnidarians.

The central nervous system of bilaterians coordinates the actions of muscles, which allows coordinated movement of appendages and body parts. This coordination of muscles permits highly effective and efficient movement on land, in water, or through the air. The central nervous system is also essential for the processing of sensory information gathered from a wide variety of sensory systems. Many animals have sensory systems for detecting light, for forming images of their environment (sight), for mechanical touch, for detecting movement, for detecting sounds (hearing), for detecting electric fields, and for chemical detection (e.g., taste and smell). These sensory systems allow animals to find food, and the ability of animals to move allows them to capture or collect food from their environment. These same abilities also allow most animals to move to avoid potential predators or to search for suitable mates. Most animals can also assess the suitability of different environments and move appropriately in response to that information.

Media Clip 30.1 Nervous Systems Lead to Efficient Predators

www.Life11e.com/mc30.1

30.2 recap

The body plans of animals are variations on patterns of symmetry, body cavity structure, segmentation, appendages, and nervous systems.

learning outcomes

You should be able to:

- Explain how differences in body symmetry, body cavities, nervous system organization, segmentation, and appendages among animals are functionally related to movement and feeding.
-
1. Why is bilateral symmetry strongly associated with cephalization, the concentration of sensory organs in an anterior head?
 2. Explain several ways in which body cavities, segmentation, and centralized nervous systems improve control over movement.

Many of the modifications to the body plans of animals affect their ways of finding, capturing, and processing food. Evolutionary changes in symmetry, body cavities, appendages, segmentation, and sensory systems have played key roles in enabling animals to obtain food from their environment as well as helping them avoid becoming food for other animals.

30.3 Animals Use Diverse Forms of Movement to Feed

As we noted in [Key Concept 30.1](#), animals are heterotrophs, or “other-feeders.” Although some animals rely on photosynthetic endosymbionts to nourish them (see Investigating Life: Can Corals Reacquire Dinoflagellate Endosymbionts Lost to Bleaching? in [Chapter 26](#)), most animals must expend energy to obtain an outside source of nutrition, otherwise known as food.

focus your learning

Plant eaters are called herbivores.

Predators possess features that enable them to capture and subdue their prey.

Parasites obtain nutrients by living on or within a host organism.

The need to locate food has favored the evolution of sensory structures that provide animals with detailed information about their environment as well as nervous systems that can receive, process, and coordinate that information. Furthermore, in order to acquire food, animals must either move through the environment to where food is located, or move the environment and the food it contains to them. Animals that move from one place to another are [motile](#); animals that stay in one place are [sessile](#).

motile (mo' tul) Able to move from one place to another. (Contrast with sessile.)

sessile (sess' ul) [L. *sedere*: to sit] Permanently attached; not able to move from one place to another. (Contrast with motile.)

The principal feeding strategies that animals use fall into five broad categories:

- . [Filter feeders](#) (or [suspension feeders](#)) strain small organisms from their environment.

filter feeder An organism that feeds on organisms much smaller than itself that are suspended in water or air by means of a straining device. Also called suspension feeder.

suspension feeders An organism that feeds on organisms much smaller than itself that are suspended in water or air by means of a straining device. Also called filter feeder.

- . [Herbivores](#) eat plants or parts of plants.

herbivore (ur' bi vore) [L. *herba*: plant + *vorare*: to devour] An animal that eats plant tissues. (Contrast with carnivore, detritivore, omnivore.)

- . [Predators](#) capture and eat other animals.

predator An organism that kills and/or consumes individuals (or parts of individuals) of another species (its prey).

- . **Parasites** live in or on other, generally much larger, organisms, from which they obtain energy and nutrients.

parasite [Gk. *parasitos*: one who eats at another's table] An organism that kills and/or consumes parts of an organism much larger than itself (known as its host). Parasites sometimes, but not always, kill their host.

- . **Detritivores** feed on dead organic material.

detritivore (di try' ti vore) [L. *detritus*: worn away + *vorare*: to devour] An organism that obtains its energy from the dead bodies or waste products (**detritus**) of other organisms, releasing nutrients and energy. (Contrast with carnivore, herbivore, omnivore.)

Each of these strategies can be found in many different animal groups, and none of them is limited to a single group. Individuals of some species employ more than one of these feeding strategies, and some animals employ different feeding strategies at different stages of their life cycle. The constant and ongoing need to obtain food, the variety of nutrient sources available in a given environment, and the necessity of competing with other animals to obtain food means that a variety of feeding strategies can be found among all the major animal groups.

Filter feeders capture small prey

Air and water often contain small organisms and organic molecules that are potential food for animals. Moving air and water may carry those items to an animal that positions itself in a good location. Other animals can move through the environment, filtering out prey items as they move. In either case, filter feeders use some kind of straining device to filter the food from the environment.?

Many sessile aquatic animals rely on water currents to bring prey to them ([Figure 30.8A](#)). Some sessile filter feeders (such as sponges; see [Figure 30.2](#)) expend energy to move water past their food-capturing devices. Motile filter feeders move their bodies to the nutrient source. Flamingos, for example, use their serrated beaks to filter small organisms out of the muddy mixture they pick up as they wade through shallow water. Baleen whales—the largest animals that have ever lived—are filter feeders that strain tiny crustaceans from the water column as they swim ([Figure 30.8B](#)).

Figure 30.8 Filter-Feeding Strategies (A) Sessile marine filter feeders such as this Christmas tree worm, a polychaete (annelid), allow the ocean currents to bring their food — plankton—to them. (B) The southern right whale is a motile filter feeder that strains small crustaceans such as krill from the oceans for its food.

 Media Clip 30.2 **Filter Feeders** www.Life11e.com/mc30.2

Herbivores eat plants

An individual plant has many different structures — leaves, wood, roots, sap, flowers, fruits, nectar, and seeds—that animals can consume. Not surprisingly, then, many different kinds of herbivores — animals that feed only on plants—may feed on a single kind of plant, consuming different parts of the plant or feeding on the same part in different ways. Whereas an individual animal that is captured by a predator is likely to die, herbivores often feed on plants without killing them.

Animals do not need to expend energy subduing and killing plants in order to feed on them. However, plant matter can be difficult to digest and can pose special challenges to terrestrial herbivores because the dominant land plants tend to have several different kinds of tissues, many of which are tough or fibrous. Herbivorous animals typically have long, ***complex guts** to accomplish the tasks involved in digesting plants. Animals also must expend energy to detoxify plants' defensive chemicals.

Predators and omnivores capture and subdue prey

Predators possess features that enable them to capture and subdue other animals (referred to as their **prey**). Many vertebrate predators have sensitive sensory organs that enable them to locate prey, as well as sharp teeth or claws that allow them to capture and subdue prey (**Figure 30.9**). Predators may stalk and pursue their prey or wait (often camouflaged) for their prey to

come to them.

prey [L. *praeda*: booty] An organism killed and/or consumed by a predator as an energy source.

(A)

(B)

Figure 30.9 Active and Sit-and-Wait Predators (A) The appendages (legs and wings) of the merlin along with its strong beak, are adaptations to the life of an active predatory hunter. (B) The crocodile typically sit motionless in the water, waiting in one spot for unsuspecting prey to walk within striking range.

Media Clip 30.3 Detritivores www.Life11e.com/mc30.3

Omnivores (“all-devouring”) are animals, such as raccoons and humans, that eat both plants and other animals. The diets of some omnivores differ at different life stages; many songbirds, for example, eat fruit or seeds as adults but feed insects to their young.

omnivore [L. *omnis*: everything + *vorare*: to devour] An organism that feeds on multiple

trophic levels; also an organism that feeds on animals and primary producers. (Contrast with carnivore, detritivore, herbivore.)

Parasites live in or on other organisms

Parasites obtain nutrients from another organism—a **host**—by living on or within the host. Some animal parasites consume parts of the host itself (such as ticks that suck body fluids); others hijack nutrients the host would otherwise consume (such as tapeworms that may live in the intestines of mammals). Most animal parasites are much smaller than their hosts, and many parasites can consume parts of their host without killing it. To set up residence within a host, a parasite must first overcome the host's defenses. Parasites often have complex life cycles that rely on multiple hosts, as you will see in [Key Concept 30.4](#).

host An organism that harbors a parasite or symbiont and provides it with nourishment.

Parasites that live inside their hosts are called endoparasites, and these are often morphologically very simple. Endoparasites often function without a digestive system, absorbing their food directly from the host's gut or body tissues. Many flatworms are endoparasites of humans and other mammals, as we will describe in [Chapter 31](#).

Parasites that live outside their hosts are called ectoparasites; they are generally more complex morphologically than endoparasites. Ectoparasites have digestive tracts and mouthparts that enable them to pierce the host's tissues or suck on the host's body fluids. Fleas and ticks are ectoparasitic arthropods that feed on many vertebrates, including humans.

Detritivores live on the remains of other organisms

Detritivores feed on the dead bodies or waste products of other organisms, organic matter known as **detritus**. Detritivores (sometimes called decomposers) perform an important ecosystem function by breaking down dead organic matter and returning the nutrients it contains to the environment in a form that can be used by other organisms. Detritivores are common in any soil with high organic content, as well as on the ocean floor. Well-known detritivores include earthworms and other annelids, millipedes, and many insects and crustaceans.

Charles Darwin became fascinated with earthworms and wrote a book called *The Formation of Vegetable Mould through the Action of Worms*. He was particularly impressed by the importance of earthworms in soil formation. Darwin conducted many interesting experiments to establish how quickly earthworms break down organic matter and build up rich soils.

30.3 recap

Animals are heterotrophs that must expend energy to acquire food from their environment. Most animals either move through the environment to where food is located or move the environment and the food it contains to them.

learning outcomes

You should be able to:

- Summarize common adaptations of herbivores.
- Summarize features that predators use to capture and subdue their prey.
- Distinguish among predators, parasites, and filter feeders.

1. How can you distinguish among filter feeders, predators, and parasites—all of which may feed on other animals?
2. What adaptations are necessary for animals that eat plants? What adaptations are needed for a predatory lifestyle?

As an animal grows from a single-celled zygote into a larger, more complex adult, its body structure, its diet, and the environment in which it lives may all change. In the next section we will describe some animal life cycles and discuss why they are so varied.

30.4 Animal Life Cycles Involve Trade-Offs

The life cycle of an animal encompasses its embryonic development, birth, growth to maturity, reproduction, and death. During its life an individual animal ingests food, grows, interacts with other individuals of the same and other species, and reproduces.

focus your learning

Direct development and metamorphosis each have advantages under different conditions.

Life cycles often involve trade-offs.

Animal colonies can provide some of the same specializations provided by multicellularity.

Many animal life cycles feature specialized life stages

In some groups of animals, newborns look much like miniature versions of the adults (a pattern called **direct development**). Newborns of most animal species, however, differ dramatically from adults. Many animal species have a life stage called a **larva** (plural *larvae*), which is an immature form that the animal takes early in its life before assuming an adult form. Some of the most striking life cycle changes are found among insects such as beetles, flies, moths, butterflies, and bees, which undergo radical change (called **complete metamorphosis**) between their larval and adult stages (**Figure 30.10**). In these animals, one stage may be specialized for feeding and the other for reproduction. Adults of many moth species, for example, do not eat. In some animal species, individuals eat during all life cycle stages, but what they eat changes with the stage. For example, butterfly larvae (known as caterpillars) eat leaves and flowers, whereas most adult butterflies eat only nectar. Having different life cycle stages that are specialized for different activities may increase the efficiency with which an animal performs those activities and reduce the competition for food between juveniles and adults.

direct development Pattern of development (notably among insects) in which hatchlings look like miniature versions of adults. (Contrast with metamorphosis.)

larva (plural: larvae) [L. *lares*: guiding spirits] An immature stage of any animal that differs dramatically in appearance from the adult.

complete metamorphosis A change of state during the life cycle of an organism in which the body is almost completely rebuilt to produce an individual with a very different body form. Characteristic of insects such as butterflies, moths, beetles, ants, wasps, and flies.

(A) Larva

(B) Pupa

(C) Adult

Figure 30.10 A Life Cycle with Complete Metamorphosis (A) The larval stage (caterpillar) of the cecropia moth (*Hyalophora cecropia*) is specialized for feeding. (B) The pupa is the stage during which the transformation to the adult form occurs. (C) The adult moth is specialized for dispersal and reproduction and does not feed.

Most animal life cycles have at least one dispersal stage

At some time during their lives, most animals move, or are moved, so few animals die exactly where they were born. Movement of organisms away from a parent organism or from an existing

population is called **dispersal**.

dispersal Movement of individuals into (immigration) or out of (emigration) an existing population.

Animals that are sessile as adults typically disperse as eggs or larvae. Most sessile marine animals discharge their eggs and sperm into the water, where fertilization takes place. A larva soon hatches and floats freely in the plankton, where it filters small food items from the water. Many animals that live on the seafloor, including polychaete worms and mollusks, have a radially symmetrical larval form known as a **trochophore** (Figure 30.11A). Other animals, such as crustaceans, have a bilaterally symmetrical larval form called a **nauplius** (Figure 30.11B). Both types of larvae feed for some time in the plankton and may travel long distances before settling on the ocean floor and transforming into adults.

trochophore (troke' o fore) [Gk. *trochos*: wheel + *phoreus*: bearer] A radially symmetrical larval form typical of annelids and mollusks, distinguished by a wheel-like band of cilia around the middle.

nauplius (naw' plee us) [Gk. *nauplios*: shellfish] A bilaterally symmetrical larval form typical of crustaceans.

(A) Trochophore

(B) Nauplius

Figure 30.11 Planktonic Larval Forms of Marine Animals (A) The trochophore (“wheel-bearer”) is a distinctive larval form found in several marine animal clades with spiral cleavage, most notably the polychaete worms and the mollusks. **(B)** This nauplius larva will mature into a crustacean with a segmented body and jointed appendages.

Other animal species that are motile as adults disperse when they are mature. A caterpillar, for example, may spend its entire larval stage feeding on a single plant, but after it metamorphoses into a flying adult—a butterfly or moth—it may fly to and lay eggs on other plants located far from the one where it spent its caterpillar days. In some species, individuals disperse during several different life cycle stages.

Parasite life cycles facilitate dispersal and overcome host defenses

Animals that live as endoparasites are bathed in the nutritious tissues of their host or in the digested food that fills their host’s digestive tract. Thus they may not need to exert much energy to obtain food, but to survive they must overcome the host’s defenses. Furthermore, either they or their offspring must disperse to new hosts while their host is still living, because they die when their host dies.

The fertilized eggs of some parasites are voided with the host’s feces and later ingested directly by other host individuals. Most parasite species, however, have complex life cycles involving one or more intermediate hosts and several larval stages ([Figure 30.12](#)). Some intermediate hosts transport individual parasites directly between other host species. Others house and support the parasite until another host ingests them. Complex life cycles may thus facilitate the transfer of individual parasites among hosts.

Figure 30.12 Reaching a New Host by a Complex Route The broad fish tapeworm *Diphyllobothrium latum* must pass through the bodies of a copepod (a type of crustacean) and at least one fish before it can reinfect its primary host, a mammal. Such complex life cycles assist the parasite's colonization of new host individuals, but they also provide opportunities for humans to break the cycle with hygienic measures (such as thoroughly cooking food to kill the parasites).

Some animals form colonies of genetically identical, physiologically integrated individuals

Most people tend to view the distinction between individuals and populations as clear-cut. In several groups of animals, however, asexual reproduction without fission leads to the formation of colonies composed of many physiologically integrated individuals. At first appearance, these colonies may look much like a single integrated organism. The individuals in the colony are clonal copies of one another, so they are genetically homogeneous.

Coloniality has arisen several times among animal groups, with widely varying levels of integration and specialization among the individuals. In some species, colonies are composed of loosely connected but integrated individuals that all function alike ([Figure 30.13](#)). In other colonial species, the individuals may become specialized for different functions, just as different

cell types in multicellular organisms do. The Portuguese man-of-war (a cnidarian; see [Figure 30.20](#)) is an example of such a colonial animal, as it is composed of many individuals of four different specialized body forms, all integrated and functioning together. The individuals in the colony are themselves multicellular, however, unlike the cells of a single multicellular organism.

Reteporella couchii

Figure 30.13 Colonial Animals This bryozoan colony consists of many asexually reproducing, genetically homogeneous, physiologically interacting individuals. The colony looks much like a single individual with many parts, but in fact is a group of individuals acting together.

No life cycle can maximize all benefits

A common saying, “a jack-of-all-trades is master of none,” suggests why there are constraints on the evolution of life cycles. The characteristics an animal has in any one life cycle stage may improve its performance in one activity but reduce its performance in another—a situation known as a trade-off. An animal that is good at filtering small food items from the water, for example, is unlikely to be good at capturing large prey. Similarly, energy devoted to building protective structures such as shells cannot be used for growth.

Some major trade-offs can be seen in animal reproduction. Some animals produce large numbers of small eggs, each with a small energy store ([Figure 30.14A](#)). Other animals produce a small number of large eggs, each with a large energy store ([Figure 30.14B](#)). With a fixed amount of energy available for reproduction, a female animal can produce many small eggs or a few large eggs, but she cannot produce many large eggs. Thus there is a trade-off between the number of offspring produced and the energy resources each offspring receives from its mother.

Figure 30.14 Many Small or Few Large Allocation of energy to eggs requires tradeoffs. **(A)** This European common frog has divided her reproductive energy among a large number of small eggs. **(B)** This king penguin has invested all of her reproductive energy in one large egg.

Q: What are the respective advantages and disadvantages of these two reproductive strategies?

The larger the energy store in an egg, the longer an offspring can develop before it must either find its own food or be fed by its parents. Birds of all species lay relatively small numbers of relatively large eggs, but incubation periods vary. In some species, eggs hatch when the young are still helpless ([Figure 30.15A](#)). Such **altricial** young must be fed and cared for until they can feed themselves; parents can provide for only a small number of altricial offspring. In contrast, some bird species incubate their eggs longer, and the hatchlings are developed to the point that they are able to forage for themselves almost immediately ([Figure 30.15B](#)). The young of such species are called **precocial**.

(A) *Turdus migratorius*

(B) *Anser anser*

Figure 30.15 Helpless or Independent (A) The altricial young of the common robin are essentially helpless when they hatch. Their parents feed and care for them for several weeks. (B) Graylag goose hatchlings are precocial, ready to swim and feed independently almost immediately after hatching.

altricial Born or hatched in a relatively undeveloped state that requires care and feeding by the parents.

precocial Born or hatched in a relatively advanced state that allows a high degree of independence from the parents.

30.4 recap

Many animals have life cycle stages that differ from one another morphologically. In some animals, the larval form is a dispersal stage; in other animals, the adults are more likely to disperse than are larvae. In several groups of organisms, asexual reproduction without fission leads to coloniality.

learning outcomes

You should be able to:

- Using examples, show why trade-offs can constrain evolution.
 - Compare and contrast multicellularity and coloniality.
-

1. Why can't a life cycle evolve that maximizes all aspects of feeding and reproduction simultaneously?
2. How does a colony of unicellular animals differ from a multicellular animal?

Variations in body symmetry, body cavity structure, life cycles, patterns of development, and survival strategies differentiate millions of animal species. In the remainder of this chapter and in [Chapters 31](#) and [32](#), we will become acquainted with the major animal groups and learn how the general characteristics we have just described apply to each of them.

30.5 The Root of the Animal Tree Provides Clues to Early Animal Diversification

The bilaterians make up a large monophyletic group embracing all animals other than ctenophores, sponges, placozoans, cnidarians, and a few poorly known groups of parasitic animals (see [Table 30.1](#)). Some of the traits that support the monophyly of bilaterians are the presence of three distinct cell layers in embryos (triploblasty) and the presence of at least seven Hox genes (see [Chapter 19](#)). Although bilateral symmetry is often viewed as a synapomorphy of bilaterians (and the trait gives the group its name), some groups of cnidarians are also bilaterally symmetrical. Recent studies have shown that the genetic basis of bilateral symmetry in bilaterians and in those cnidarian groups that have this trait is similar, so this feature may have been present in the ancestor of both groups.

focus your learning

Some major features common among animal groups appear to have evolved independently several times.

In many respects, sponges are the simplest animals.

Placozoan simplicity appears to be secondarily derived.

Placozoans are difficult to observe in nature because of their small size and transparency.

Bilaterian animals can be divided into the two major clades mentioned earlier, the protostomes and the deuterostomes. These two groups, as well as the remaining animal groups we will discuss below, have been diversifying separately for at least 700 million years. We will describe the protostomes in [Chapter 31](#) and the deuterostomes in [Chapter 32](#).

The remainder of this chapter describes those animal groups that are not bilaterians. The ctenophores, sponges, and placozoans have weakly differentiated tissue layers or even undifferentiated layers, and two of these groups (sponges and placozoans) also lack a nervous system. The remaining animals (those that don't fall into any of the groups mentioned thus far) are called **eumetazoans**. Eumetazoans typically have some form of body symmetry, a gut, a nervous system, and tissues organized into distinct organs (although there have been secondary losses of some of these features in some eumetazoans).

Activity 30.2 **Sponge and Diploblast Classification** www.Life11e.com/ac30.2

Ctenophores are the sister group of all other animals

Ctenophores, also known as comb jellies, were until recently thought to be most closely related to the cnidarians (jellyfish, corals, and their relatives). But ctenophores lack most of the Hox genes and many other genes found in all other animals, and recent studies of their genomes provide strong evidence that ctenophores were the earliest lineage to split from the remaining animals (**Investigating Life: Reconstructing Animal Phylogeny from Protein-Coding Genes**). This position in the animal tree does not imply that ctenophores look anything like the ancestral animal, however. All living ctenophores are quite closely related to one another, and they have been evolving for as long as all other animal lineages—ever since animals last shared a common ancestor more than 700 million years ago. Thus many traits of modern ctenophores

are highly derived and specialized.

Ctenophores have a radially symmetrical, diploblastic body plan. The two cell layers are separated by an inert, gelatinous extracellular matrix called **mesoglea**. Ctenophores, unlike sponges, have a **complete gut**: food enters through a mouth, and wastes are eliminated through two anal pores.

mesoglea (mez' uh glee uh) [Gk. *mesos*: middle + *gloia*: glue] A thick, gelatinous noncellular layer that separates the two cellular tissue layers of ctenophores, cnidarians, and scyphozoans.

complete gut A gut with an entrance and a separate exit.

Ctenophores move by beating cilia rather than by muscular contractions. Most of the 250 known species have eight comblike rows of cilia-bearing plates, called **ctenes** (Figure 30.16). Recent studies of the many genes that encode nervous systems indicate that these genes were duplicated and specialized separately in ctenophores, cnidarians, and bilaterians. This finding suggests that nervous systems evolved independently in these three groups in response to similar selection pressures associated with multicellularity, movement, and prey capture.

ctene (teen) [Gk. *cteis*: comb] In ctenophores, a comblike row of cilia-bearing plates. Ctenophores move by beating the cilia on their eight ctenes.

(A) Generalized anatomy of a ctenophore

(B) *Mnemiopsis leidyii*

Figure 30.16 Comb Jellies Feed with Tentacles (A) The body plan of a typical ctenophore. The long, sticky tentacles sweep through the water, efficiently harvesting small prey. **(B)** This comb jelly, photographed in Sydney Harbor, Australia, has short tentacles. Comb jellies get their name from the ctenes — rows or “combs” of cilia used for movement.

The feeding tentacles of ctenophores are covered with cells that discharge adhesive material when they contact prey. After capturing its prey, a ctenophore retracts its tentacles to bring the food to its mouth. In some species, the entire surface of the body is coated with sticky mucus that captures prey. Most ctenophores eat small planktonic organisms, although some eat other ctenophores. They are common in open seas and can become abundant in coastal bays, where large populations of ctenophores may inhibit the growth of other organisms.

Ctenophore life cycles are uncomplicated. Gametes are released into the gut and discharged through the mouth or the anal pores. Fertilization takes place in open seawater. In nearly all species, the fertilized egg develops directly into a miniature ctenophore, which gradually grows into an adult.

 Media Clip 30.4 Ctenophores www.Life11e.com/mc30.4

Sponges are loosely organized animals

In several respects, **sponges** are the simplest animals. For this reason, they were long thought to be the sister group of the remaining animals, until genome sequencing placed the ctenophores in that position. But some of the perceived complexity of ctenophores now appears to have evolved independently from other animal lineages, whereas sponges have retained more of the features of the ancestral animal. Although sponges have some specialized cells, they have no distinct embryonic cell layers and no true organs. Early naturalists classified sponges as plants because they were sessile and lacked body symmetry.

▶ investigatinglife Reconstructing Animal Phylogeny from Protein-Coding Genes

experiment

Original Paper: Dunn, C. W. et al. 2008. Broad phylogenomic sampling improves resolution of the Animal Tree of Life, *Nature* 452: 745–749.

Several breakthroughs in our understanding of animal phylogeny have occurred in recent years as the sequences of genes and proteins have been compared across species. Casey Dunn and his colleagues compared sequences from many different proteins across a wide variety of animal groups to reconstruct their phylogeny.

QUESTION► What is the earliest split in the animal tree? Are ctenophores, sponges, or placozoans the sister group of other animals?

METHOD

1. Collect mRNA from major groups of animals and choanoflagellate outgroups. (See Figure 30.2 to see why choanoflagellates were used as an outgroup.)
2. Reverse transcribe the mRNA into cDNA.
3. Sequence the cDNA, translate the genes into the amino acid sequences of the proteins, and align sequences of homologous proteins.
4. Reconstruct the phylogeny of the animal groups from the aligned protein sequences.

RESULTS

The tree below represents just a sample of the major lineages examined by Dunn and colleagues.

CONCLUSION► The earliest split in the animal tree was between ctenophores and the remaining animals.

work with the data

The table below includes a small sample of the data collected and analyzed by Dunn and his colleagues. Use these representative data to reconstruct a tree of the represented species. In the original paper, Dunn and colleagues reported on 11,234 amino acid positions among 77 species of animals. Twenty-seven of these amino acid positions for 11 of those species are shown in the table. (See Table 3.2 for the one-letter amino acid abbreviations.)

QUESTIONS►

1. Construct a phylogenetic tree of these 11 species using the parsimony method. Use the out-group (a choanoflagellate) to root your tree. Assume that all changes from one amino acid to another are equally likely. See Key Concept 21.2 for a review of the parsimony method of reconstructing phylogenetic trees.
2. How many character state changes (i.e., changes from one amino acid to another) occur along each branch on your tree?
3. Which characters support the ctenophores as the sister group of the remaining animals?
4. Which group on your tree represents the bilaterian animals? The protostomes? The deuterostomes?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Sponges have hard skeletal elements called **spicules**, which may be small and simple or large and complex (see [Figure 30.2B](#)). Three major groups of sponges, which separated soon after the origin of sponges, are distinguished by their spicules. Members of two groups (glass sponges and demosponges) have skeletons composed of siliceous spicules made of hydrated silicon dioxide ([Figure 30.17A](#) **!!and B**). These spicules are remarkable in having greater flexibility and toughness than synthetic glass rods of similar length. Members of the third group, the calcareous sponges, take their name from their calcium carbonate spicules ([Figure 30.17C](#)). There is some question about the monophyly of sponges, although genomic analyses that combine information from many genes support their monophyly.

spicule [L. arrowhead] A hard, calcareous skeletal element typical of sponges.

(A) *Aplysina fistularis*

(B) *Euplectella aspergillum*

(C) *Sycon* sp.

Spicules

Figure 30.17 Sponge Diversity (A) The majority of sponge species are demosponges, such as these yellow tube sponges. The system of pores and water canals (see [Figure 30.2B](#)) that is typical of the sponge body plan is apparent in this photograph. **(B)** The supporting structures of both demosponges and glass sponges are siliceous spicules, seen here in the skeleton of a glass sponge. **(C)** The spicules of calcareous sponges are made of calcium carbonate.

The body plan of sponges of all three groups—even large ones, which may reach 1 meter or more in length—is an aggregation of cells built around a water canal system. Sponges bring water into their bodies by beating the flagella of their specialized feeding cells, called **choanocytes** (see [Figure 30.2B](#)). Water, along with any food particles it contains, enters the sponge by way of small pores and passes into the water canals or a central atrium, where the choanocytes capture food particles. (You may recall from [Key Concept 30.1](#) that the choanocytes are similar in structure to protists known as choanoflagellates, which may indicate a retained ancestral similarity between the two groups.)

choanocyte (ko' an uh site) The collared, flagellated feeding cells of sponges.
--

A skeleton of simple or branching spicules, often combined with a complex network of elastic fibers, supports the body of most sponges. Sponges also produce an extracellular matrix, composed of collagen, adhesive glycoproteins, and other molecules, that holds the cells together. Most species are filter feeders; a few species are predators that trap prey on hook-shaped spicules that protrude from the body surface.

Most of the 8,500 species of sponges are marine animals; only about 50 species live in fresh water. Sponges come in a wide variety of sizes and shapes that are adapted to different movement patterns of water. Sponges living in intertidal or shallow subtidal environments with strong wave action are firmly attached to the substrate. Most sponges that live in slowly flowing water are flattened and are oriented at right angles to the direction of current flow. They intercept water and the food items it contains as it flows past them.

Sponges reproduce both sexually and asexually. In most species, a single individual produces both eggs and sperm, but individuals do not self-fertilize. Water currents carry sperm from one individual to another. Sponges also reproduce asexually by budding and fragmentation.

Placozoans are abundant but rarely observed

As discussed at the start of this chapter, **placozoans** are (like sponges) structurally very simple animals with only a few distinct cell types ([Figure 30.18A](#)). Individuals in the mature, asymmetrical life stage are usually observed adhering to surfaces (such as the glass of aquariums, where they were first discovered, or to rocks and other hard substrates in nature). Their structural simplicity—they have no mouth, gut, or nervous system—initially led to yet another hypothesis about the earliest split among the animals. Phylogenetic analyses and some aspects of the placozoans' structural simplicity, however, suggest that placozoan simplicity may be secondarily derived. They are generally considered to have a diploblastic body plan, with upper and lower surface layers that sandwich a layer of contractile fiber cells.

(A)

(B)

Figure 30.18 Placozoan Simplicity (A) As seen in this artist's rendition, adult placozoans are tiny (1-2 mm across), flattened, asymmetrical animals. **(B)** Recent studies have found a symmetrical, weakly swimming pelagic stage of placozoan to be abundant in many warm tropical and subtropical seas.

Recent studies have found that placozoans have a pelagic (open-ocean) life stage that is capable of swimming ([Figure 30.18B](#)), but the life history of placozoans is incompletely known. Most studies have focused on the larger adherent stages that are most easily observed in aquariums. The transparent nature and small size of placozoans make them very difficult to observe in nature. Nonetheless, it is known that placozoans can reproduce both asexually and sexually, although the details of their sexual reproduction are poorly understood. As we noted at the opening of this chapter, placozoans have been studied mainly in aquariums, where they appear after being inadvertently collected with other marine organisms, although we now know that pelagic-stage placozoans are abundant in warm seas around the world.

Cnidarians are specialized predators

The **cnidarians** (jellyfish, sea anemones, corals, and hydrozoans) make up the largest and most diverse group of non-bilaterian animals. The mouth of a cnidarian is connected to a blind sac called the **gastrovascular cavity** (a cnidarian thus does not have a complete gut). The gastrovascular cavity functions in digestion, circulation, and gas exchange, and it also acts as a hydrostatic skeleton. The single opening serves as both mouth and anus.

gastrovascular cavity Serving for both digestion (gastro) and circulation (vascular); in particular, the central cavity of the body of jellyfish and other cnidarians.

The life cycle of many cnidarians has two distinct stages, one sessile and the other motile ([Figure 30.19](#)), although one or the other of these stages is absent in some groups. In the

sessile **polyp** stage, a cylindrical stalk attaches the animal to the substrate. The motile **medusa** (plural *medusae*) is a free-swimming stage shaped like a bell or an umbrella. It typically floats with its mouth and feeding tentacles facing downward.

Figure 30.19 The Life Cycle of Most Cnidarians Has Two Stages The life cycle of a scyphozoan (jellyfish) exemplifies the typical cnidarian body forms: the sessile, asexual polyp and the motile, sexual medusa. Some species of cnidarians have life cycles that lack polyps or medusae.

Animation 30.1 Life Cycle of a Cnidarian www.Life11e.com/a30.1

polyp (pah' lip) [Gk. *poly*: many + *pous*: foot] In cnidarians, a sessile, asexual life cycle stage.

medusa (plural: medusae) In cnidarians, a free-swimming, sexual life cycle stage shaped like a bell or an umbrella.

Mature polyps produce medusae by asexual budding. Medusae then reproduce sexually, producing eggs or sperm by meiosis and releasing the gametes into the water. A fertilized egg develops into a free-swimming, ciliated larva called a **planula**, which eventually settles to the bottom and develops into a polyp.

planula (plan' yew la) [L. *planum*: flat] A free-swimming, ciliated larval form typical of the

cnidarians.

Cnidarians are specialized predators adapted for capturing and subduing relatively large and complex prey. As we noted earlier in discussing ctenophores, recent genome studies suggest that the nerve nets found in cnidarians are largely independently derived from those found in ctenophores, as well as from the nervous systems found in bilaterians. The tentacles of cnidarians are covered with specialized cells that contain stinging organelles called **nematocysts**, which inject toxins into their prey (**Figure 30.20**). Some cnidarians, including many corals and anemones, gain additional nutrition from photosynthetic endosymbionts that live in their tissues.

nematocyst (ne mat' o sist) [Gk. *nema*: thread + *kystis*: cell] An elaborate, threadlike structure produced by cells of jellyfishes and other cnidarians, used chiefly to paralyze and capture prey.

(A) Portuguese man-of-war
(*Physalia physalis*)

(B)

Cnidocytes

Once discharged, stylets and spines on the **nematocyst** anchor it to the prey.

Figure 30.20 Nematocysts Are Potent Weapons (A) The tentacles of the Portuguese man-of-war, a hydrozoan, are rife with specialized cells called cnidocytes. These cells

contain stinging organelles called nematocysts, which inject toxins into their prey. The Portuguese man-of-war is a colonial organism, composed of many physiologically integrated individuals with specialized functions. **(B)** Nematocysts of the Portuguese man-of-war cause painful reactions when they come into contact with human skin.

Cnidarians have cells containing muscle fibers whose contractions enable the animals to move, as well as simple nerve nets that integrate the body's activities. Their bodies also contain specialized structural molecules (collagen, actin, and myosin). Yet cnidarians, like ctenophores, are largely made up of inert mesoglea. Most species have low metabolic rates and can survive in environments where they encounter prey only infrequently.

Of the roughly 12,500 living cnidarian species, all but a few live in the oceans ([Figure 30.21](#)). The smallest cnidarians can barely be seen without a microscope. One small group, known as myxozoans, consists of tiny parasites, usually with a two-host life cycle that includes a fish and an annelid worm or a bryozoan. The largest known jellyfish is 2.5 meters in diameter, and some colonial hydrozoans (which include the Portuguese man-of-war; see [Figure 30.20](#)) can reach lengths in excess of 30 meters. Here we describe the three clades of cnidarians that contain the most species: anthozoans, scyphozoans, and hydrozoans.

ANTHOZOANS

Members of the **anthozoan** clade include sea anemones, sea pens, and corals. Sea anemones (see [Figure 30.21A](#)), all of which are solitary, are widespread in both warm and cold ocean waters. Sea pens (see [Figure 30.21B](#)), by contrast, are colonial. Each colony consists of two or more different kinds of polyps. The primary polyp has a lower portion anchored in the bottom sediment and a branched upper portion that projects above the substrate. Along the upper portion, the primary polyp produces smaller secondary polyps by budding. Some of these secondary polyps differentiate into feeding polyps; in some species, other secondary polyps differentiate to circulate water through the colony.

(A) *Urticina crassicornis*

(B) *Virgularia gustaviana*

(C) *Phyllorhiza punctata*

(D) *Obelia* sp.

Figure 30.21 Diversity among Cnidarians (A) Sea anemones are sessile, living attached to marine substrates. Water currents carry prey into the nematocyst-studded tentacles. (B) The sea pen is a colonial cnidarian that lives in soft bottom sediments and projects polyps above the substrate. (C) This jellyfish illustrates the complexity of a scyphozoan medusa. (D) Polyp colonies of this hydrozoan grow on rocks of intertidal pools.

The common names of coral groups — brain corals, staghorn corals, and organ pipe corals, among others—often describe their appearance ([Figure 30.22A](#)). Corals are sessile and colonial. The polyps of most species form a skeleton by secreting a matrix of organic molecules on which they then deposit calcium carbonate. As the colony grows, old polyps die, but their calcium carbonate skeletons remain. Living corals form a layer on top of a growing bank of skeletal remains, eventually forming chains of islands and reefs. The Great Barrier Reef along the northeastern coast of Australia is a system of coral formations more than 2,000 kilometers long, which is about the distance from New York City to St. Louis ([Figure 30.22B](#)). A single coral reef in the Red Sea has been calculated to contain more material than all the buildings in the major cities of North America combined.

(A) *Symphyllia* sp.

(B)

Figure 30.22 Corals (A) The descriptive common name of this Caribbean coral is “brain coral.” **(B)** Many different coral species form the Great Barrier Reef off the coast of Australia.

Corals flourish at shallow depths in clear, nutrient-poor tropical waters. They grow well in such environments because unicellular photosynthetic dinoflagellates live endosymbiotically within their cells. These dinoflagellates provide the corals with products of photosynthesis; the corals, in turn, provide the dinoflagellates with nutrients and a place to live. This endosymbiotic relationship explains why reef-forming corals are restricted to clear surface waters, where light levels are high enough to support photosynthesis.

Coral reefs throughout the world are threatened by rising CO₂ levels (which result in increased ocean temperatures and acidification of ocean waters through the formation of carbonic acid). Polluted runoff from development on adjacent shorelines is an additional threat to corals. Warmer temperatures lead to the loss of * coral endosymbionts (known as coral bleaching), and acidification can cause coral skeletons to dissolve. An overabundance of nitrogen from fertilizer in runoff is advantageous to algae, which overgrow and eventually smother the corals.

SCYPHOZOANS

The several hundred species of **scyphozoans** are all marine. The mesoglea of their medusae is thick and firm, giving rise to their common name of jellyfish (or sea jellies). The medusa rather than the polyp dominates the life cycle of scyphozoans. An individual medusa is male or female, releasing eggs or sperm into the open sea. A fertilized egg develops into a small planula larva that quickly settles on a substrate and develops into a small polyp. This polyp feeds and grows and may produce additional polyps by budding. After a period of growth, the polyp begins to bud off small medusae, which feed, grow, and transform into adult medusae (see [Figures 30.19](#) and [30.21C](#)).

HYDROZOANS

The polyp typically dominates the life cycle of **hydrozoans**, but some species have only medusae and others have only polyps. Most hydrozoans are colonial. A single planula larva eventually gives rise to a colony of many polyps, all interconnected and sharing a continuous gastrovascular cavity ([Figure 30.23](#)). Within such a colony, some polyps have tentacles with many nematocysts; they capture prey for the colony. Other individuals lack tentacles and are unable to feed, but are specialized for the asexual production of medusae. Still others are fingerlike and defend the colony with their nematocysts.

Figure 30.23 Many Hydrozoans Are Colonial The polyps in a hydrozoan colony may differentiate to perform specialized tasks. In the species whose life cycle is diagrammed here, the medusa is the sexual reproductive stage, producing eggs and sperm in organs called gonads.

Some small groups of parasitic animals may be the closest relatives of bilaterians

Two small groups of tiny marine parasites are listed in [Table 30.1](#) but are not depicted in the phylogeny in [Figure 30.1](#): the orthonectids and the rhombozoans. Recent genomic analyses suggest that these groups may be among the closest surviving relatives of the bilaterians, although their exact phylogenetic placement is uncertain. Both groups are highly reduced parasites that lack many of the structures that traditionally have been used to study animal relationships. As their genomes become more completely known, the relationships of these two groups to other animals should become clearer. Two other small groups (also listed in [Table 30.1](#) but not shown in [Figure 30.1](#)) have been proposed as also falling just outside the bilaterians: the xenoturbellids and acoels. Some genomic analyses, however, suggest that these animals are actually highly specialized deuterostomes.

30.5 recap

Bilaterian animals are classified into two major clades, protostomes and deuterostomes. The non-bilaterian animals comprise the ctenophores, sponges, placozoans, cnidarians, and

some small groups of parasitic animals.

learning outcomes

You should be able to:

- Apply knowledge of phylogenetic relationships among major groups of animals to describe the evolution and loss of major structural features.
- Apply information about the life histories of major animal groups to design methods for studying them.

1. What is the basis for the claim that animal nervous systems evolved independently in ctenophores, cnidarians, and bilaterians?
2. Why are sponges and placozoans considered to be animals even though they lack the complex body structures found in most other animal groups?
3. The discoveries that the pelagic stages of placozoans are abundant in warm seas and that the mature stages settle on smooth surfaces suggest how these organisms might be collected and surveyed. What sampling procedures might you use to discover whether placozoans occur at a particular location along a coast?

QA Which animal groups are involved in the earliest split in the animal tree?

Three major hypotheses have been proposed in recent decades about the earliest split in the animal tree. Given the structural simplicity of sponges and their similarity to some animal outgroups (especially choanoflagellates), for many years biologists considered sponges to form the sister group of all other animals. When placozoans were first described, their structural simplicity also led other biologists to suspect that they, rather than sponges, were the sister group of other animals. In contrast, the ctenophores share some superficial similarities with cnidarians and were traditionally considered to be more closely related to them, rather than splitting earlier at the base of the animal tree. However, as biologists collected complete genomes from all these lineages, it became clearer that the simplicity of sponges and placozoans derives from a mix of ancestral retained features and secondarily derived losses of complexity. For example, although placozoans, with only four cell types and no true organs, are structurally less complex than ctenophores, this structural simplicity is now thought to represent an evolutionary reversal in the placozoan lineage. In contrast, some of the “advanced” features of ctenophores (such as their nervous systems) were gained through independent gene duplications and specializations compared with the nervous systems of cnidarians and bilaterians. As we explored in Investigating Life: Reconstructing Animal Phylogeny from Protein-Coding Genes, phylogenetic analyses of many genes now suggest that ctenophores are the sister group of all other animals.

Future directions

As biologists collect more genomes from new species of animals, it is becoming possible to reconstruct the various gene duplications and changes that have led to the major structural and functional differences among animal groups. Having several independent origins of nervous systems is a boon for understanding how nervous systems arise and evolve. The understanding and study of these genomes is just beginning, but already complete genomes are shedding considerable light on the origins of animal complexity.

► 30.1 Some Animal Characteristics Evolved More Than Once

- Animals share a set of derived traits not found in other groups of organisms. These traits include similarities in the sequences of many of their genes, the structure of their cell junctions, and the components of their extracellular matrix.
- Several features common to most living animals, including multicellularity, motility, and nervous systems, evolved independently in different lineages. In particular, the decentralized [nerve nets](#) of ctenophores and cnidarians evolved independently of the [central nervous systems](#) of bilaterians.

nerve nets Diffuse, loosely connected aggregations of nervous tissues in certain non-bilaterialian animals such as cnidarians.

central nervous system (CNS) That portion of the nervous system that is the site of most information processing, storage, and retrieval; in vertebrates, the brain and spinal cord. (Contrast with peripheral nervous system.)

- Patterns of embryonic development provide clues to the evolutionary relationships among animals. [Diploblastic](#) animals, which include the ctenophores, placozoans, and cnidarians, develop two embryonic cell layers. The [monoblastic](#) sponges lack embryonic cell layer differentiation, whereas the [triploblastic](#) animals develop three cell layers.

Review Figure 30.1

diploblastic Having a body derived from only two embryonic cell layers (ectoderm and endoderm, but no mesoderm) (Contrast with monoblastic, triploblastic.)

monoblastic Having a body derived from a single embryonic cell layer. (Contrast with diploblastic, triploblastic.)

triploblastic Having a body derived from three embryonic cell layers (ectoderm, mesoderm, and endoderm). (Contrast with diploblastic, monoblastic.)

- Differences in their patterns of early development characterize two major triploblastic clades, the **protostomes** and the **deuterostomes**.
- **Sponges** are structurally simple animals that lack well-differentiated cell layers and true organs. They have skeletons made up of siliceous or calcareous [spicules](#). They create water currents and capture food with flagellated feeding cells called [choanocytes](#).

Review Figure 30.2

spicule [L. arrowhead] A hard, calcareous skeletal element typical of sponges.

choanocyte (ko' an uh site) The collared, flagellated feeding cells of sponges.

► 30.2 Animals Diverged with Distinct Body Plans

- Animal [body plans](#) can be described in terms of [symmetry](#), **body cavity** structure,

[segmentation](#), types of appendages, and nervous system development.

body plan The general structure of an animal, the arrangement of its organ systems, and the integrated functioning of its parts.

symmetry Pertaining to an attribute of an animal body in which at least one plane can divide the body into similar, mirror-image halves. (See bilateral symmetry, radial symmetry.)

segmentation Division of an animal body into segments.

- A few animals have no symmetry, but most animals have either [radial symmetry or bilateral symmetry](#). **Review Figure 30.5**

radial symmetry The condition in which any two halves of a body are mirror images of each other, providing the cut passes through the center; a cylinder cut lengthwise down its center displays this form of symmetry.

- Most bilaterally symmetrical animals exhibit [cephalization](#): the concentration of sensory organs and nervous tissues in an anterior head.

cephalization (sef ah luh zay' shun) [Gk. *kephale*: head] The evolutionary trend toward increasing concentration of brain and sensory organs at the anterior end of the animal.

- On the basis of their body cavity structure, animals can be described as [acoelomates](#), [pseudocoelomates](#), or [coelomates](#). **Review Figure 30.6, Activity 30.1**

acoelomate An animal that does not have a coelom.

pseudocoelomate (soo' do see' low mate) [Gk. *pseudes*: false + *koiloma*: cavity] Having a body cavity, called a pseudocoel, consisting of a fluid-filled space in which many of the internal organs are suspended, but which is enclosed by mesoderm only on its outside.

coelomate Possessing a coelom.

- Segmentation, which takes many forms, improves control of movement, as do appendages. The development of a nervous system is important for the coordination of muscular movement and the processing of sensory information.

► 30.3 Animals Use Diverse Forms of Movement to Feed

- [Motile](#) animals can move to find food; [sessile](#) animals stay in one place but may expend energy to move the environment and the food it contains to them

motile (mo' tul) Able to move from one place to another. (Contrast with sessile.)

sessile (sess' ul) [L. *sedere*: to sit] Permanently attached; not able to move from one place to another. (Contrast with motile.)

- [Filter feeders](#) strain small organisms and organic molecules from their environment.

filter feeder An organism that feeds on organisms much smaller than itself that are suspended in water or air by means of a straining device. Also called suspension feeder.

- **Herbivores** consume plants, usually without killing them.

herbivore (ur' bi vore) [L. *herba*: plant + *vorare*: to devour] An animal that eats plant tissues. (Contrast with carnivore, detritivore, omnivore.)

- **Predators** have morphological features such as sharp teeth, beaks, and claws that enable them to capture and subdue animal **prey**.

predator An organism that kills and/or consumes individuals (or parts of individuals) of another species (its prey).

prey [L. *praeda*: booty] An organism killed and/or consumed by a predator as an energy source.

- **Parasites** live in or on other organisms and obtain nutrition from those **host** individuals.

parasite [Gk. *parasitos*: one who eats at another's table] An organism that kills and/or consumes parts of an organism much larger than itself (known as its host). Parasites sometimes, but not always, kill their host.

host An organism that harbors a parasite or symbiont and provides it with nourishment.

- **Detritivores** consume dead organic matter and return the nutrients it contains to the ecosystem.

detritivore (di try' ti vore) [L. *detritus*: worn away + *vorare*: to devour] An organism that obtains its energy from the dead bodies or waste products (**detritus**) of other organisms, releasing nutrients and energy. (Contrast with carnivore, herbivore, omnivore.)

► 30.4 Animal Life Cycles Involve Trade-Offs

- The stages of an animal's life cycle may be specialized for different activities. An immature stage whose morphology is dramatically different from that of the adult stage is called a **larva**.

larva (plural: larvae) [L. *lares*: guiding spirits] An immature stage of any animal that differs dramatically in appearance from the adult.

- Most animal life cycles have at least one **dispersal** stage. Many sessile marine animals can be grouped by the presence of one of two distinct larval dispersal stages: **trochophore** or **nauplius**. **Review Figure 30.11**

dispersal Movement of individuals into (immigration) or out of (emigration) an existing population.

trochophore (troke' o fore) [Gk. *trochos*: wheel + *phoreus*: bearer] A radially symmetrical larval form typical of annelids and mollusks, distinguished by a wheel-like band of cilia around the middle.

nauplius (naw' plee us) [Gk. *nauplios*: shellfish] A bilaterally symmetrical larval form typical of crustaceans.

- A characteristic of an animal or a life cycle stage may improve the animal's performance in one activity but reduce its performance in another, a situation known as a trade-off.
- Parasites have complex life cycles that may involve one or more hosts and several larval stages. **Review** [Figure 30.12](#)
- In some groups of animals, asexual reproduction without fission leads to the formation of colonies composed of many genetically homogeneous, physiologically integrated individuals.

▶ 30.5 The Root of the Animal Tree Provides Clues to Early Animal Diversification

- **Ctenophores** are radially symmetrical and have two cell layers separated by an inert extracellular matrix called [mesoglea](#). Their weakly differentiated organ systems are independently derived from those in eumetazoans. **Review** [Figure 30.16](#)

mesoglea (mez' uh glee uh) [Gk. *mesos*: middle + *gloia*: glue] A thick, gelatinous noncellular layer that separates the two cellular tissue layers of ctenophores, cnidarians, and scyphozoans.

- **Eumetazoans** have well-developed organ systems and include all animals except ctenophores, sponges, and placozoans. The triploblastic protostomes and deuterostomes belong to a large monophyletic group called **bilaterians**. **Review** [Figure 30.1](#), **Investigating Life: Reconstructing Animal Phylogeny from Protein-Coding Genes, Activity 30.2**
- **Placozoans** are asymmetrical as adults. They have only a few cell types and lack true organs, although some features of their simplicity may be secondarily derived.
- The life cycle of most **cnidarians** has two distinct stages: a sessile [polyp](#) stage and a motile [medusa](#) stage that reproduces sexually. A fertilized egg develops into a free-swimming [planula](#) larva, which settles to the bottom and develops into a polyp. **Review** [Figures 30.19](#), [30.23](#), [Animation 30.1](#)

polyp (pah' lip) [Gk. *poly*: many + *pous*: foot] In cnidarians, a sessile, asexual life cycle stage.

medusa (plural: medusae) In cnidarians, a free-swimming, sexual life cycle stage shaped like a bell or an umbrella.

planula (plan' yew la) [L. *planum*: flat] A free-swimming, ciliated larval form typical of the cnidarians.

Review

0.4 Direct development and metamorphosis each have advantages under different conditions.

0.4 Life cycles often involve trade-offs.

Original Papers: Ma, X. and J. E. Purcell. 2005. Temperature, salinity, and prey effects on polyp versus medusa bud production by the invasive hydrozoan *Moerisia lyonsi*. *Marine Biology* 147: 225-234.

Schmich, J., Y. Kraus, D. De Vito, D. Graziussi, F. Boero and S. Piraino. 2007. Induction of reverse development in two marine Hydrozoans. *International Journal of Developmental Biology* 51: 45-56.

In many ways, *Turritopsis dohrnii* is similar to many other marine cnidarians: It's a small (5 mm in diameter) hydrozoan that drifts freely around warm ocean waters. It begins its life as a motile planula larva and grows into a sessile polyp when it finds a suitable substrate. Once it reaches adulthood, it develops into a motile, bell-shaped medusa capable of sexual reproduction. However, adults of *T. dohrnii* are capable of undergoing something strange: they can revert back to a younger version of themselves, rejuvenating and becoming “immortal jellies” ([Figure A](#)).

Figure A

Individuals of *T. dohrnii* in the medusa stage undergo this reversal by reactivating genetic instructions from earlier in their life cycles to develop polyp cells. These polyp cells develop into sessile, asexual polyps, which then produce new motile, sexual medusae. Scientists curious about what triggers this unusual phenomenon hypothesized that some cnidarians may “throw their life cycle in reverse” if starving, injured, or facing stressors in their environment.

To test their hypothesis, scientists simulated unfavorable environmental conditions by incubating animals for 3 hours in different concentrations of cesium chloride (CsCl), which causes chemical disruptions in the function of various essential medusa cell types. Each treatment group included 30–50 specimens. All developmental assays, which categorize the life stages of specimens (medusa, reducing medusa, polyp), were performed multiple times to confirm the results. (A “reducing medusa” is a medusa that has started to revert back into a polyp.) Each treatment group showed a significant increase in the possibility of reverse

development, compared with the control group ([Figure B](#)). Bars show 95% confidence intervals.

Figure B

Questions

1. What conclusions can you draw from the data represented in the graph? What purpose do you think reverse development serves for some cnidarians?
2. Describe the reproductive and locomotive differences between medusa and polyp forms of cnidarians. Use this information to predict a possible trade-off that cnidarians face if they undergo reverse development.
3. In a different species of cnidarian (*Moerisia lyonsi*), individuals are also capable of maintaining polyp or medusa forms, depending on environmental conditions. One population of this species lives in an area of high food abundance, and the other lives in an area of low food abundance. Would you expect the two populations to look different? Explain your answer.

Protostome Animals

The majority of described species of life are protostomes, largely because of the enormous diversity of insects. Beetles alone account for almost one quarter of all described species.

key concepts

- [L.1 Protostomes Account for More Than Half of All Described Species](#)
- [L.2 Many Lophotrochozoans Have Ciliated Feeding Structures or Life Stages](#)
- [L.3 Ecdysozoans Grow by Shedding Their Cuticles](#)
- [L.4 Arthropods Are the Most Abundant and Diverse Group of Animals](#)

Exploring the Diversity of Life on Earth

Of the 1.8 million species of life that have been discovered and named by biologists, a large majority are protostomes. One group of protostomes, the insects, accounts for more than 1 million of these species, or more than half of all known species of living organisms. Although these numbers may seem incredibly large, they represent a relatively small fraction of the total protostome diversity that is thought to exist on Earth.

As recently as the 1980s, many biologists thought that about half of existing insect species had been described, but today they think that the number of described insect species may be a much smaller fraction of the total number of living species. Why did they change their minds?

A simple but important field study suggested that the number of existing insect species had been significantly underestimated. Knowing that the insects of tropical rainforests—the most species-rich habitat on Earth—were poorly known, entomologist Terry Erwin made a comprehensive sample of one group of insects, the beetles, in the canopies of a single species of tropical forest tree, *Luehea seemannii*, in Panama. Erwin fogged the canopies of large *L. seemannii* trees with an insecticide and collected the insects that fell from the trees in collection nets. He collected about 1,200 species of beetles—many of them previously undescribed—from this one species of tree.

Erwin then used a set of assumptions to estimate the total number of insect species in tropical rainforests. His assumptions included estimates of the number of species of trees in these forests; the proportion of beetles that specialize on a specific species of host tree; the relative proportion of beetles to other insect groups; and the proportion of beetles that live in trees versus those that live in leaf litter on the ground. From this and similar studies, Erwin estimated that there may be 30 million or more species of insects on Earth. Although recent tests of Erwin's assumptions suggest that 30 million was an overestimate, it is clear that the vast majority of insect species remain to be discovered.

Erwin's pioneering study highlighted the fact that we live on a poorly known planet, most of whose species have yet to be named and described. Much of that undiscovered diversity occurs among several groups of protostomes.

QA Which groups of protostomes are thought to contain the most undiscovered species?

31.1 Protostomes Account for More Than Half of All Described Species

You may recall that the embryos of diploblastic animals (the ctenophores, placozoans, and cnidarians, which we discussed in [Chapter 30](#)) have two cell layers: an outer ectoderm and an inner endoderm (see [Key Concept 30.1](#)). Sometime after the origin of the diploblastic animals, a third embryonic cell layer evolved: the mesoderm, which lies between the ectoderm and the endoderm. Mesoderm is found in the two major triploblastic animal clades, the protostomes and the deuterostomes. If we were to judge solely on the basis of numbers, both of species and of individuals, the protostomes would emerge as by far the more successful of the two groups.

focus your learning

Ecdysozoans have an external covering—a cuticle—that they must shed as they grow. Arthropods have a rigid exoskeleton and have made use of a great variety of appendages.

As noted in [Key Concept 30.1](#), the name “protostome” means “mouth first.” In protostomes, the embryonic blastopore becomes the mouth as the animal develops. In contrast, in deuterostomes (“mouth second”), the blastopore becomes the anal opening of the gut. The protostomes are extremely varied, but they are all bilaterally symmetrical animals whose bodies exhibit two major derived traits:

- . An anterior brain that surrounds the entrance to the digestive tract
- . A ventral nervous system consisting of paired or fused longitudinal nerve cords

Other aspects of protostome body organization differ widely from group to group ([Table 31.1](#)). Before gene sequences were available for phylogenetic analysis, biologists considered the structure of the body cavity to be a critical feature in animal classification. But the results of genetic analyses have shown that body cavity forms have undergone considerable convergence in the course of protostome evolution. Although the common ancestor of the protostomes had a coelom, subsequent modifications of the coelom distinguish many protostome lineages. In some lineages (such as the flatworms and entoprocts), the coelom has been lost (that is, these groups re-verted to an acoelomate state). Some lineages are characterized by a pseudocoel, a body cavity lined with mesoderm in which the internal organs are suspended (see [Figure 30.6B](#)). In two of the most prominent protostome clades, the coelom has been highly modified:

table 31.1 Anatomical Characteristics of Some Major Protostome Groups

Group	Body cavity	Digestive tract	Circulatory system
Arrow worms	Coelom	Complete	None
Lophotrochozoans			
Bryozoans	Coelom	Complete	None
Entoprocts	None	Complete	None
Flatworms	None	Blind gut	None
Rotifers	Pseudocoel	Complete	None
Gastrotrichs	Pseudocoel	Complete	None

Ribbon worms	Coelom	Complete	Closed

Horsehair worms	Pseudocoel	Greatly reduced	None
Arthropods	Hemocoel	Complete	Open

Arthropods lost the ancestral condition of the coelom over the course of evolution. Their internal body cavity has become a [hemocoel](#), or “blood chamber,” in which fluid from an open circulatory system bathes the internal organs before returning to blood vessels.

hemocoel The primary body cavity of many invertebrates, which contains circulatory fluid.

Most mollusks have an open circulatory system with some of the attributes of the hemocoel, but they retain vestiges of an enclosed coelom around their major organs.

The protostomes can be divided into two major clades—the lophotrochozoans and the ecdysozoans—largely on the basis of DNA sequence analysis ([Figure 31.1](#)).

Figure 31.1 Phylogenetic Tree of Protostomes Two major lineages, the lophotrochozoans and the ecdysozoans, dominate the protostome tree. Some small groups are not included in this tree. The phylogenetic relationships shown here are supported mainly by genomic sequence data. Although genomic studies are contributing greatly to our knowledge of animal phylogeny, most species of protostomes have yet to be studied in detail.

Activity 31.2 **Protostome Classification** www.Life11e.com/ac31.2

Activity 31.1 **Features of the Protostomes** www.Life11e.com/ac31.1

Cilia-bearing lophophores and trochophores evolved among the

lophotrochozoans

Lophotrochozoans derive their name from two different ciliated features: a feeding structure known as a lophophore and a freeliving larval form known as a trochophore. Neither the lophophore nor the trochophore is universal to all lophotrochozoans, however.

Several distantly related groups of lophotrochozoans (including bryozoans, entoprocts, brachiopods, and phoronids) have a **lophophore**, a circular or U-shaped ring of ciliated, hollow tentacles around the mouth (**Figure 31.2**). This complex organ is used for both food collection and gas exchange. Biologists once grouped taxa that have lophophores together as “lophophorates,” but it is now clear that they are not one another’s closest relatives. The lophophore appears to have evolved independently at least twice, or else it is an ancestral feature of lophotrochozoans and has been lost in many groups. Nearly all animals with a lophophore are sessile as adults. They use the tentacles and cilia of the lophophore to capture small floating organisms from the water. Other sessile lophotrochozoans have less well developed tentacles that they use for the same purpose.

lophophore A U-shaped fold of the body wall with hollow, ciliated tentacles that encircles the mouth of animals in several different groups. Used for filtering prey from the surrounding water.

Plumatella repens

Figure 31.2 Bryozoans Use the Lophophore to Feed The extended lophophore dominates the anatomy of the colonial bryozoans. This species inhabits fresh water, although most bryozoans are marine.

Media Clip 31.1 **Feeding with a Lophophore** www.Life11e.com/mc31.1

Some lophotrochozoans, especially in their larval form, use cilia for locomotion. The larval form known as a **trochophore** moves by beating a band of cilia (see **Figure 30.11A**). This movement of cilia also brings plankton closer to the larva, where it can capture and ingest them (its cilia are therefore similar in function to the cilia of the lophophore). Trochophore larvae are found among many of the major groups of lophotrochozoans, including the mollusks, annelids,

ribbon worms, entoprocts, and bryozoans. This larval form was probably present in the common ancestor of lophotrochozoans but has been subsequently lost in several lineages.

trochophore (troke' o fore) [Gk. *trochos*: wheel + *phoreus*: bearer] A radially symmetrical larval form typical of annelids and mollusks, distinguished by a wheel-like band of cilia around the middle.

Some lophotrochozoans (including flatworms, ribbon worms, annelids, and mollusks) exhibit spiral ***cleavage** in early development, in which layers of new cells spiral obliquely around the axis of the animal-vegetal pole of the early embryo. Some biologists group these taxa together as “spiralian,” although phylogenetic analyses of gene sequences do not support monophyly of taxa with spiralian cleavage. Nonetheless, spiral cleavage may have been present in the lophotrochozoan ancestor and subsequently lost in several descendant lineages.

Many lineages of lophotrochozoans have a wormlike body form, which means that they are bilaterally symmetrical, legless, soft-bodied, and at least several times longer than they are wide. A wormlike body form enables animals to burrow efficiently through marine sediment or soil. However, as you will see in [Key Concept 31.2](#), the mollusks—the most familiar of the lophotrochozoans to many people — have a very different body organization.

Ecdysozoans must shed their cuticles

Ecdysozoans have an external covering, or **cuticle**, that is secreted by the underlying epidermis (the outermost cell layer). The cuticle provides these animals with both protection and support. Once formed, however, the cuticle cannot grow. How, then, can ecdysozoans increase in size? They do so by shedding, or **molting**, the cuticle and replacing it with a new, larger one.

cuticle (1) In plants, a waxy layer on the outer body surface that retards water loss. (2) In ecdysozoans, an outer body covering that provides protection and support and is periodically molted.

molting The process of shedding part or all of an outer covering, as the shedding of feathers by birds or of the entire exoskeleton by arthropods.

 Media Clip 31.2 **Molting a Cuticle** www.Life11e.com/mc31.2

A fossil Cambrian arthropod preserved in the process of molting shows that molting evolved more than 500 million years ago ([Figure 31.3A](#)). An increasingly rich array of molecular and genetic evidence, including a set of Hox genes shared by all ecdysozoans, suggests they have a single common ancestor. Thus molting of a cuticle is a trait that may have evolved only once during animal evolution.

(A) Fossil evidence of molting

(B) Whip scorpion (*Heterophrynus batesii*) undergoing molting

Figure 31.3 Molting: Past and Present (A) This 500-million-year-old fossil from the Cambrian, an individual of a long-extinct arthropod species captured in the process of molting, shows that the molting process is an evolutionarily ancient trait. (B) This tailless whip scorpion has just emerged from its discarded exoskeleton. It will be highly vulnerable until its new cuticle has hardened.

Before an ecdysozoan molts, a new cuticle is already forming underneath the old one. Once the old cuticle is shed, the new one expands and hardens. Until it has hardened, though, the animal is vulnerable to its enemies, both because its outer surface is easy to penetrate and because an individual with a soft cuticle can move only slowly or not at all ([Figure 31.3B](#)).

The cuticles of some ecdysozoans, mainly arthropods, function as external skeletons, or **exoskeletons**. These exoskeletons are thickened by layers of protein and a strong, waterproof polysaccharide called **chitin**. An animal with a rigid, chitin-reinforced exoskeleton can neither move in a wormlike manner nor use cilia for locomotion. A hard exoskeleton also impedes the passage of oxygen and nutrients into the animal, presenting new challenges in other areas besides growth. Thus new mechanisms of locomotion and gas exchange evolved in those

ecdysozoans with hard exoskeletons.

exoskeleton (eks' oh skel' e ton) [Gk. *exos*: outside + *skleros*: hard] A hard covering on the outside of the body to which muscles are attached. (Contrast with endoskeleton.)

chitin (kye' tin) [Gk. *kiton*: tunic] The characteristic tough but flexible organic component of the exoskeleton of arthropods, consisting of a complex, nitrogen-containing polysaccharide. Also found in cell walls of fungi.

To move rapidly, an animal with a rigid exoskeleton must have body extensions that can be manipulated by muscles. Such appendages evolved in the late Precambrian, leading to the **arthropod** ("jointed foot") clade. Arthropod appendages exist in an amazing variety of forms. They serve many functions, including walking and swimming, gas exchange, food capture and manipulation, copulation, and sensory perception. Arthropods grasp food with their mouths and associated appendages and digest it internally. Their muscles are attached to the inside of the exoskeleton. Each segment has muscles that operate that segment and the appendages attached to it ([Figure 31.4](#)).

Figure 31.4 Arthropod Skeletons Are Rigid and Jointed This cross section through a thoracic segment of a generalized arthropod illustrates the arthropod body plan, which is characterized by a rigid exoskeleton with jointed appendages.

The arthropod exoskeleton has had a profound influence on the evolution of these animals. Encasement within a rigid body covering provides support for walking on dry land, and the waterproofing provided by chitin keeps the animal from dehydrating in dry air. Thus aquatic arthropods were, in short, excellent candidates to invade terrestrial environments. As you will see, they did so several times.

Arrow worms retain some ancestral developmental features

Nearly all triploblastic animal groups can be readily classified as either protostomes or deuterostomes, but the evolutionary relationships of one small group, the **arrow worms**, were debated for many years. The blastopore of arrow worms develops into an anus (as in deuterostomes), but they have ventral nerve cords and spiral cleavage (as in many protostomes). Recent studies of gene sequences, however, clearly identify arrow worms as protostomes. There is still some question as to whether they are the closest relatives of the lophotrochozoans (as shown in [Figure 31.1](#)) or possibly the sister group of all other protostomes.

The arrow worm body is divided into three compartments: head, trunk, and tail ([Figure 31.5](#)). The body is transparent or translucent. Most arrow worms swim in the open sea. A few species live on the seafloor. Their abundance as fossils indicates that they were common more than 500 million years ago. The 180 or so known living species of arrow worms are small enough—ranging from 3 millimeters to 12 centimeters in length—that their gas exchange and waste excretion requirements are met by diffusion through the body surface. They lack a circulatory system; wastes and nutrients are moved around the body in the coelomic fluid, which is propelled by cilia that line the coelom.

(B)

Spadella cephaloptera

Figure 31.5 An Arrow Worm Arrow worms have a three-part body organization. Their fins and grasping spines are adaptations for a predatory lifestyle. Individuals are hermaphroditic, producing both eggs in an ovary and sperm in a testis.

Arrow worms are hermaphroditic; that is, each individual produces both male and female gametes. In most species, eggs are fertilized internally following elaborate courtship between two individuals, although some species can self-fertilize. Miniature adults hatch directly from the eggs; these animals have no distinct larval stage.

Arrow worms are stabilized in the water by means of one or two pairs of lateral fins and a tail fin. They are major predators of planktonic organisms in the open ocean, ranging in size from small protists to young fish as large as the arrow worms themselves. An arrow worm typically lies motionless in the water until water movement signals the approach of prey. The arrow worm then darts forward and uses the stiff spines adjacent to its mouth to grasp its prey.

31.1 recap

The shared derived traits of protostomes include a blastopore that develops into a mouth (except in arrow worms), an anterior brain, and a ventral nervous system. Several lophotrochozoan groups are characterized by a filter-feeding ciliated structure known as a lophophore or by cilia-bearing larvae known as trochophores. Ecdysozoans, which have a body covering known as a cuticle, must molt periodically in order to grow.

learning outcomes

You should be able to:

- Synthesize the consequences of having a hard body covering versus a soft body for life as an animal.
- Describe major evolutionary innovations among protostomes that are related to life in aquatic versus terrestrial environments.

1. How does an animal's body covering influence the way it exchanges gases, feeds, and moves?
2. What features make arthropods well adapted for colonizing terrestrial environments?

In the next section we continue our survey of the protostomes with a more detailed look at the major groups of lophotrochozoans and the diverse body forms that are found among them.

***connect the concepts** As described in [Key Concept 44.2](#), cleavage is the sequence of early cell divisions that transforms the diploid zygote into a mass of undifferentiated cells that will develop into the embryo. Different patterns of cleavage result in differential distributions of nutrients and cytoplasmic determinants within the egg cytoplasm.

31.2 Many Lophotrochozoans Have Ciliated Feeding Structures or Life Stages

Lophotrochozoans come in a variety of sizes and shapes, ranging from relatively simple animals with a blind gut (that is, a gut with only one opening) and no internal transport system to animals with a complete gut (having separate entrance and exit openings) and a complex internal transport system. They include some species rich groups, such as flatworms, annelids, and mollusks. A number of these groups have wormlike bodies, but the lophotrochozoans encompass a wide variety of morphologies, including a few groups with external shells. Some lophotrochozoan groups have only recently been discovered by biologists.

focus your learning

Flatworms have flat bodies because they lack specialized organs for transporting oxygen to their internal tissues.

Most annelids lack a rigid external protective covering and instead have a thin, permeable body wall that serves as a surface for gas exchange.

Modifications of the shell, mantle, and foot have allowed mollusks to diversify in a wide variety of environments.

Most bryozoans and entoprocts live in colonies

Most of the 5,500 known species of **bryozoans** (“moss animals”) and 170 known species of **entoprocts** (meaning “anus inside”) are colonial animals that live in a “house” made of material secreted by the external body wall. The colonial species are sessile, but the few solitary species can slowly move around in their environment. Almost all bryozoans and entoprocts are marine, although a few species occur in fresh or brackish water.

A bryozoan colony consists of many small (1-2 mm) individuals connected by strands of tissue along which nutrients can be moved. Bryozoan colonies can grow to contain more than 2 million individuals, all stemming from the asexual reproduction of the colony's founder. Rocks in coastal regions in many parts of the world are covered with luxuriant growths of bryozoans. Some bryozoans create miniature reefs in shallow waters. In some species, the individual colony members are differentially specialized for feeding, reproduction, defense, or support. Individual bryozoans in a colony are able to oscillate their lophophore to increase contact with prey. They can also retract it into their "house" (see [Figure 31.2](#)).

Bryozoans can reproduce sexually by releasing sperm into the water, which carries the sperm to other individuals. Eggs are fertilized internally; developing embryos are brooded before they exit as larvae to seek suitable sites for attachment to the substrate. Entoprocts can also reproduce asexually. Some species of entoprocts release unfertilized eggs into the water for fertilization, whereas other species brood their developing young as bryozoans do.

Bryozoans and entoprocts differ in the placement of the anus. In bryozoans, the anus is located outside the ring of tentacles that make up the lophophore, whereas the anus of entoprocts is located in the center of this ring. The lophophores of the two groups also function differently: food particles are carried from the tips to the bases of the tentacles in bryozoans, but from the bases to the tips of the tentacles in entoprocts. Entoprocts lack a coelom, whereas bryozoans have a three-part coelom.

Flatworms, rotifers, and gastrotrichs are structurally diverse relatives

Flatworms, rotifers, gastrotrichs, and their close relatives are a structurally diverse group of organisms whose relationships to one another have been hypothesized only recently. Recent genomic studies show that this monophyletic lophotrochozoan group includes both acoelomate subgroups (e.g., the flatworms) and pseudocoelomate subgroups (e.g., the rotifers and gastrotrichs), and yet the closest relatives of this group—the bryozoans and entoprocts—are coelomate and acoelomate, respectively. Thus this group provides an example of the evolutionary convergence in body cavity form that we described in [Key Concept 31.1](#).

FLATWORMS

Flatworms lack specialized organs for transporting oxygen to their internal tissues. In the absence of a gas transport system, each cell must be near a body surface, a requirement met by the dorsoventrally flattened body form that gives these animals their common name. The digestive tract of a free-living flatworm consists of a mouth opening into a blind gut. The gut is often highly branched, forming intricate patterns that increase the surface area available for the absorption of nutrients. Some small free-living flatworms are cephalized, with a head bearing chemoreceptor organs, two simple eyes, and a tiny brain composed of anterior thickenings of the longitudinal nerve cords. Free-living flatworms glide over surfaces on a layer of mucus, powered by broad bands of cilia ([Figure 31.6A](#)).

(A) *Eurylepta californica*,
a free-living flatworm

(B) Diagram of a typical parasitic flatworm

Figure 31.6 Flatworms Include Both Parasites and Free-Living Forms (A) Some flatworm species, such as this Pacific marine flatworm, are free-living. (B) The fluke diagrammed here lives endoparasitically in the gut of sea urchins and is typical of endoparasitic flatworms. Because their hosts provide all the nutrition they need, these internal parasites do not require elaborate feeding or digestive organs and can devote most of their bodies to reproduction.

Although many flatworms are free-living, most flatworm species are parasites. Of the parasitic species, most are endoparasites. There are also flatworms that feed externally on animal tissues (living or dead), and some graze on plants. A likely evolutionary transition was from feeding on dead organisms to feeding on the body surfaces of dying hosts to invading and consuming parts of healthy hosts.

Most of the 30,000 known species of living flatworms tapeworms and flukes; members of these two groups are endoparasites, particularly of vertebrates ([Figure 31.6B](#)). Because they absorb digested food from the digestive tracts of their hosts, many endoparasitic flatworms lack digestive tracts of their own. Some cause serious human diseases, such as schistosomiasis, which is common in parts of Asia, Africa, and South America. The species that causes this devastating disease has a complex life cycle involving both freshwater snails and mammals as hosts. Members of another flatworm group, the monogeneans, are ectoparasites of fishes and other aquatic vertebrates. The turbellarians include most of the free-living species.

ROTIFERS

Most species of **rotifers** are tiny (50-500 μm long) — smaller than some ciliate protists—but they have specialized internal organs ([Figure 31.7A and B](#)). A complete gut passes from an anterior mouth to a posterior anus; the body cavity is a pseudocoel that functions as a hydrostatic skeleton. Rotifers typically propel themselves through the water by means of rapidly beating cilia rather than by muscular contraction.

(A) Rotifer anatomy

(B) *Philodina* sp.

(C) *Polymorphus marilis*

(D) *Lepidodermella* sp.

Figure 31.7 Rotifers and Gastrotrichs (A) The rotifer diagrammed here reflects the general structure of many rotifers. (B) A micrograph reveals the internal complexity of the microscopic rotifers. (C) Spiny-headed worms are parasitic rotifer relatives. The spines of the proboscis anchor the animal to the organs of its host. (D) Gastrotrichs superficially resemble rotifers but have flattened ventral surfaces covered with cilia, as flatworms do.

Media Clip 31.3 **Rotifer Feeding** www.Life11e.com/mc31.3

The most distinctive organ of rotifers is a conspicuous ciliated organ called the corona, which surmounts the head of many species. Coordinated beating of the cilia sweeps particles of organic matter from the water into the animal's mouth and down to a complicated structure called the mastax, in which food is ground into small pieces. By contracting muscles around the pseudocoel, a few rotifer species that prey on protists and small animals can protrude the mastax through the mouth and seize small objects with it.

Most of the known species of rotifers live in fresh water. Some species rest on the surfaces of mosses or lichens in a desiccated, inactive state until it rains. When rain falls, they absorb water and become mobile, feeding in the films of water that temporarily cover the plants. Most rotifers live no longer than a few weeks.

Both males and females are found in some species of rotifers, but only females are known among the bdelloid rotifers (the *b* in "bdelloid" is silent). Biologists have concluded that the bdelloid rotifers may have existed for tens of millions of years without regular sexual reproduction. Lack of genetic recombination generally leads to the buildup of deleterious mutations, so long-term **asexual reproduction** typically leads to extinction. Recent studies, however, have indicated that bdelloid rotifers may avoid this problem by picking up fragments of genes from their environment during the desiccation-rehydration cycle, which allows genetic recombination among individuals in the absence of direct sexual exchange.

A few highly reduced lineages appear to have descended from the free-living rotifers. The spiny-headed worms are parasites with complex life cycles, often parasitizing several animal hosts (**Figure 31.7C**). The jaw worms are tiny marine organisms that glide between sand grains in shallow marine environments. Although spiny-headed worms and jaw worms are structurally quite distinct, molecular analyses have revealed that both groups are essentially highly modified rotifers.

GASTROTRICHS

The 800 known species of **gastrotrichs** (also called "hairy backs") are abundant, tiny (0.05-3 mm) animals that live in marine sediments, in fresh waters, and in the water films that surround grains of soil. Their transparent bodies have a flat ventral surface that is covered with cilia (**Figure 31.7D**). Most species are simultaneous hermaphrodites, with both male and female

reproductive organs, although the male organs have been greatly reduced or lost in some species that reproduce asexually.

Ribbon worms have a long, protrusible feeding organ

Ribbon worms (nemerteans) have simple nervous and excretory systems similar to those of flatworms. Unlike flatworms, however, they have a closed circulatory system and a complete digestive tract with a mouth at one end and an anus at the other. Small ribbon worms move slowly by beating their cilia. Larger ones employ waves of muscle contraction to move over the surface of sediments or to burrow into them.

Within the body of nearly all of the 1,200 known species of ribbon worms is a fluid-filled cavity called the rhynchocoel, within which lies a hollow, muscular **proboscis**. The proboscis, which is the worm's feeding organ, may extend much of the length of the body. Contraction of the muscles surrounding the rhynchocoel causes the proboscis to evert explosively through an anterior pore (Figure 31.8A). The proboscis may be armed with sharp stylets that pierce prey and discharge paralysis-causing toxins into the wound.

proboscis An elongated nose or sucking mouthpart that is typically tubular and flexible.

Figure 31.8 Ribbon Worms (A) The proboscis is the ribbon worm's feeding organ. (B) This large marine nemertean is found in harbors and bays along the Pacific Coast of North America. Its proboscis is not everted in this photograph.

Media Clip 31.4 **Explosive Extrusion of Ribbon Worm Proboscis**
www.Life11e.com/mc31.4

Most ribbon worm species are marine, although there are species that live in fresh water or on land. Most species are less than 20 centimeters long, but individuals of some species reach 20 meters or more. Some genera feature species that are conspicuous and brightly colored (Figure 31.8B). Recent molecular analyses suggest that ribbon worms may be most closely related to

Recall that the bryozoans and entoprocts use a lophophore to feed. Brachiopods and phoron

Brachiopods (la

Figure 31.9 A Brachiopod's Lophophore The lophophore of this North Pacific brachiopod can be seen between the valves of its shell.

Most brachiopods are 4 to 6 centimeters long. They live attached to a solid substrate or embedded in soft sediments. Most species are attached by means of a short, flexible stalk that holds the animal above the substrate. Gases are exchanged across body surfaces, especially the tentacles of the lophophore. Most brachiopods release their gametes into the water, where they are fertilized. The larvae remain among the plankton for only a few days before they settle and develop into adults.

Brachiopods reached their peak abundance and diversity in Paleozoic and Mesozoic times. More than 26,000 fossil species have been described. Only about 450 species are known to survive, but they remain common in some marine environments.

PHORONIDS

The ten known species of **phoronids** are small (5-25 cm long), sessile worms that live in muddy or sandy sediments or attached to rocky substrates. Phoronids are found in marine waters from the intertidal zone to about 400 meters deep. They secrete tubes made of chitin, within which they live, and have a U-shaped gut with the anus located outside the lophophore ([Figure 31.10](#)). Their cilia drive water into the top of the lophophore, and the water exits through the narrow spaces between the tentacles. Suspended food particles are caught and transported to the mouth by ciliary action. Some species release eggs into the water, where they are fertilized, but other species produce large eggs that are fertilized internally and retained in the parent's body, where they are brooded until they hatch.

Figure 31.10 Phoronids (A) The tentacles of this phoronid's lophophores form spirals. (B) The phoronid gut is U-shaped, as seen in this generalized diagram.

Annelids have segmented bodies

The wormlike bodies of **annelids** are clearly segmented. As described in [Key Concept 30.2](#), segmentation allows an animal to move different parts of its body independently, giving it much better control of its movement. The earliest segmented worms, preserved as fossils from the middle Cambrian, were burrowing marine annelids.

In most large annelids, the coelom in each segment is isolated from those in other segments ([Figure 31.11](#)). A separate nerve center called a ganglion (plural ganglia) controls each segment; nerve cords that connect the ganglia coordinate their functioning. Most annelids lack a rigid external protective covering; instead they have a thin, permeable body wall that serves as a general surface for gas exchange. Most annelids are thus restricted to moist environments because they lose body water rapidly in dry air. The approximately 19,000 described species live in marine, freshwater, and moist terrestrial environments.

Figure 31.11 Annelids Have Many Body Segments The segmented structure of annelids such as this earthworm is apparent both externally and internally. Many organs are repeated serially.

POLYCHAETES

More than half of all annelid species are commonly known as **polychaetes** (“many hairs”), although this is a descriptive term rather than the name of a single clade. Recent molecular studies indicate that polychaetes are paraphyletic with respect to the remaining annelids. Most polychaetes are marine, and many live in burrows in soft sediments. Most of them have one or more pairs of eyes and one or more pairs of tentacles, with which they capture prey or filter food from the surrounding water, at the anterior end of the body ([Figure 31.12A](#); see also [Figure 30.7A](#)). In some species, the body wall of most segments extends laterally as a series of thin outgrowths called parapodia. The parapodia function in gas exchange, and some species use them to move. Stiff bristles called setae protrude from each parapodium, forming temporary contact with the substrate and preventing the animal from slipping backward when its muscles contract.

(B) *Riftia sp.*

(C) *Lumbricus terrestris*

(D) *Hirudo medicinalis*

Figure 31.12 Diversity among the Annelids (A) Fan worms, or “feather duster worms,” are sessile marine polychaetes that grow in masses, filtering food from the water with their tentacles. This individual has been removed from its chitinous tube. (B) Pogonophorans live around hydro-thermal vents deep in the ocean. Their tentacles can be seen protruding from their chitinous tubes. (C) Earthworms, like all oligochaetes, are hermaphroditic; when they copulate, each individual donates and receives sperm. (D) The medicinal leech has been a tool of physicians and healers for centuries. Even today, leeches have uses in clinical practice.

Members of one polychaete clade, the **pogonophorans**, secrete tubes made of chitin and other substances, in which they live ([Figure 31.12B](#)). Pogonophorans have lost their digestive tract (they have no mouth or gut). So how do they obtain nutrition? Part of the answer is that pogonophorans can take up dissolved organic matter directly from the sediments in which they live or from the surrounding water. Much of their nutrition, however, is provided by endosymbiotic bacteria that the pogonophorans house in a specialized organ known as the trophosome. These bacteria oxidize hydrogen sulfide and other sulfur-containing compounds, fixing carbon from methane in the process. Uptake of the hydrogen sulfide, methane, and oxygen used by the bacteria is facilitated by hemoglobin in the pogonophorans' tentacles. It is this hemoglobin that gives the tentacles their red coloration.

Pogonophorans were not discovered until early in the twentieth century, when the first species were discovered on the seafloor at depths of up to a few hundred meters. In recent decades, deep-sea explorers have found them living many thousands of meters below the ocean surface. In these deep oceanic sediments, they may reach densities of many thousands per square meter. About 160 species have been described. The largest and most remarkable pogonophorans are 2 meters or more in length and live near deep-sea hydrothermal vents—volcanic openings in the seafloor through which hot, sulfide-rich water pours. The methane and hydrogen sulfide from these vents provide the raw materials for carbon fixation by the pogonophorans' endosymbiotic bacteria.

CLITELLATES

The approximately 3,000 described species of **clitellates**, which form a well-supported clade within the annelids, are found in freshwater, marine, and terrestrial environments. The clitellates appear to be phylogenetically nested among various groups of polychaetes, although the exact relationships are not yet clear. There are two major groups of clitellates, the oligochaetes and the leeches.

Oligochaetes (“few hairs”) have no parapodia, eyes, or anterior tentacles, and they have only four pairs of setae bundles per segment. Earthworms—the most familiar oligochaetes—burrow in and ingest soil, from which they extract food particles. All oligochaetes are hermaphroditic. Sperm are exchanged simultaneously between two copulating individuals ([Figure 31.12C](#)). Eggs and sperm are deposited in a cocoon outside the adult's body. Fertilization occurs within the cocoon after it is shed, and when development is complete, miniature worms emerge and immediately begin independent life.

Leeches, like oligochaetes, lack parapodia and tentacles. The coelom of leeches is not divided into compartments; the coelomic space is largely filled with undifferentiated tissue. Groups of segments at each end of the body are modified to form suckers, which serve as temporary anchors that aid the leech in its movement. With its posterior sucker attached to a substrate, the leech extends its body by contracting its circular muscles. The anterior sucker is then attached, the posterior one detached, and the leech shortens itself by contracting its longitudinal muscles. Leeches live in freshwater or terrestrial habitats.

Most leeches are ectoparasites that feed by making an incision in a host, from which blood flows. A leech can ingest so much blood in a single feeding that its body may enlarge severalfold. The leech secretes an anticoagulant into the wound that keeps the host's blood flowing. For centuries, medical practitioners employed leeches to draw blood to treat diseases they believed were caused by an excess of blood or by "bad blood." Although most leeching practices (such as inserting a leech in a person's throat to alleviate swollen tonsils) have been abandoned, *Hirudo medicinalis* (the medicinal leech; [Figure 31.12D](#)) is used today to reduce fluid pressure and prevent blood clotting in damaged tissues, to eliminate pools of coagulated blood, and to prevent scarring. The anticoagulants of certain other leech species also contain anesthetics and blood vessel dilators and are being studied for possible medical uses.

Mollusks have undergone a dramatic evolutionary radiation

Mollusks are the most diverse group of lophotrochozoans, both in numbers of species and in the environments they occupy. Although the major groups of mollusks differ dramatically in morphology, they all share the same three major body components: a foot, a visceral mass, and a mantle ([Figure 31.13A](#)).

(A) Generalized molluscan body plan

(B) Chitons

(C) Gastropods

(D) Bivalves

(E) Cephalopods

Figure 31.13 Organization and Diversity of Molluscan Bodies (A) The major molluscan groups display different variations on a body plan that includes three major components: a foot, a visceral mass of internal organs, and a mantle. In many species, the mantle secretes a calcareous shell. (B) Chitons have eight overlapping calcareous plates surrounded by a girdle. (C) Most gastropods have a single dorsal shell, into which they can retreat for protection. (D) Bivalves get their name from their two hinged shells, which can be tightly closed. (E) Cephalopods are active predators; they use their arms and tentacles to capture prey. This squid has an internal shell but no external shell.

- . The molluscan foot is a large, muscular structure that originally was both an organ of locomotion and a support for the internal organs. In squids and octopuses, the foot has been modified to form arms and tentacles borne on a head with complex sensory organs. In other groups, such as clams, the foot is a burrowing organ. In some groups the foot is greatly reduced.
- . The heart and the digestive, excretory, and reproductive organs are concentrated in a centralized, internal **visceral mass**.

visceral mass The bulk of the digestive, reproductive, excretory, and respiratory systems of mollusks, contained within the shell.

- . The **mantle** is a fold of tissue that covers the organs of the visceral mass. The mantle secretes the hard, calcareous shell that is typical of many mollusks.

mantle (1) In mollusks, a fold of tissue that covers the organs of the visceral mass and secretes the hard shell that is typical of many mollusks. (2) In geology, Earth's crust below the solid lithospheric plates.

In most mollusks, the mantle extends beyond the visceral mass to form a mantle cavity. Within this cavity lie gills that are used for gas exchange. When cilia on the gills beat, they create a current of water. The tissue of the gills, which is highly vascularized (contains many blood vessels), takes up oxygen from the water and releases carbon dioxide. Many mollusk species use their gills as filter-feeding devices, whereas others feed using a rasping structure known as a **radula** to scrape algae from rocks. In some mollusks, such as the marine cone snails, the

radula has been modified into a drill or poison dart.

radula A rasplike structure used for scraping food particles off a surface.

In all mollusks except cephalopods, the blood vessels do not form a closed system. Blood and other fluids empty into a large, fluid-filled hemocoel, through which fluids move and deliver oxygen to the internal organs. Eventually the fluids reenter the blood vessels and are moved by a heart.

Monoplacophorans were the most abundant mollusks during the Cambrian period, 500 million years ago, but only a few species survive today. In monoplacophorans, in contrast to all other living mollusks, the gas exchange organs, muscles, and excretory pores are repeated over the length of the body.

The four major clades of living mollusks are the chitons, gastropods, bivalves, and cephalopods. Each of these groups is readily identifiable and distinct, even though they share variations on a common body plan.

CHITONS

Eight overlapping calcareous plates, surrounded by a structure known as the girdle, protect the internal organs and muscular foot of **chitons** (Figure 31.13B). The chiton body is bilaterally symmetrical, and the internal organs, particularly the digestive and nervous systems, are relatively simple. Most chitons are marine omnivores that scrape algae, bryozoans, and other organisms from rocks with a sharp radula. An adult chiton spends most of its life clinging tightly to rock surfaces with its large, muscular, mucus-covered foot. It moves slowly by means of rippling waves of muscular contraction in the foot. Fertilization in most chitons takes place in the water, but in a few species fertilization is internal and embryos are brooded within the body. There are approximately 1,000 living species of chitons known.

GASTROPODS

Gastropods (Figure 31.13C) are the most species-rich and widely distributed mollusks, with about 85,000 known living species. Snails, whelks, limpets, slugs, nudibranchs (sea slugs), and abalones are all gastropods. Most species move by gliding on the muscular foot, but in a few species—the sea butterflies and heteropods—the foot is a swimming organ with which the animal moves through open ocean waters.

Marine nudibranchs and terrestrial slugs are gastropods that have lost their protective shell over the course of evolution (Figure 31.14). Without a shell, these groups rely on other forms of protection from predation. The coloration of many nudibranchs is aposematic, meaning that it serves to warn potential predators of toxicity. Other nudibranch species and most terrestrial slugs exhibit camouflaged coloration.

(A) *Mexichromis macropus*

(B) *Deroceras* sp.

(C) *Octopus cyanea*

Figure 31.14 Mollusks in Some Groups Have Lost Their Shells (A) Nudibranchs (“naked gills”), also called sea slugs, are shell-less gastropods. This species is brightly colored, alerting potential predators of its toxicity. (B) Slugs are terrestrial, shell-less gastropods that feed on decomposing vegetation on the damp forest floor. (C) Octopuses have neither an external nor an internal shell, which allows these cephalopods to squeeze through tight spaces.

 Media Clip 31.6 **Octopuses Can Pass through Small Openings**
www.Life11e.com/mc31.6

Shelled gastropods have one-piece shells. The only mollusks that live in terrestrial environments—land snails and slugs—are gastropods. In these terrestrial species, the mantle tissue is modified into a highly vascularized lung.

BIVALVES

Clams, oysters, scallops, and mussels are all familiar **bivalves**. The approximately 30,000 known species are found in both marine and freshwater environments. Bivalves have a hinged, two-part shell that extends over the sides of the body as well as the top ([Figure 31.13D](#)). Many clams use the foot to burrow into mud and sand. Bivalves feed by taking in water through an opening called an incurrent siphon and filtering food from the water with their large gills, which are also the main sites of gas exchange. Water and gametes exit through the excurrent siphon. Fertilization takes place in open water in most species.

CEPHALOPODS

The **cephalopods**—squids, cuttlefish, octopuses, and nautilus—first appeared near the beginning of the Cambrian period. By the Ordovician period a variety of types were present. Today there are about 800 described living species. In these mollusks the excurrent siphon is

modified to allow the animal to control the volume of the mantle cavity and thereby bring in or expel water ([Figure 31.13E](#)). The modification of the mantle into a device for forcibly ejecting water from the cavity through the siphon enables these animals to move rapidly through the water by “jet propulsion.” With their greatly enhanced mobility, cephalopods became the major predators in the open waters of the Devonian oceans. They remain important marine predators today.

As is typical of active, rapidly moving predators, cephalopods have a head with complex sensory organs—most notably eyes that are comparable to those of vertebrates in their ability to resolve images. The head is closely associated with a large, branched foot that bears the arms and/or tentacles and a siphon. Arms are distinguished by the presence of suckers along most of their length. Tentacles, in contrast, have suckers only near the tips or lack suckers altogether. Octopuses typically have eight arms and no tentacles, whereas squids and cuttlefishes have eight arms plus two tentacles. Cephalopods use their arms and tentacles to capture and subdue prey; octopuses also use their arms to move over the substrate. The large, muscular mantle provides a solid external supporting structure. The gills hang in the mantle cavity.

Many early cephalopods had an external chambered shell divided by partitions. The only surviving cephalopods with such shells are the nautilus (genus *Nautilus*). The chambers inside nautilus shells are connected by a strand of tissue that runs through ducts in the partitions. Blood in this tissue carries water *from* the chambers and gases *into* the chambers, thus providing buoyancy. Most cephalopods retain an internal shell that functions for internal support and, in some species, is also chambered and buoyant. Octopuses have completely lost their shells, which allows them to compress their bodies through very small openings.

31.2 recap

Lophotrochozoans include animals with diverse body types. Wormlike forms include some flatworms, ribbon worms, phoronids, and annelids. There has been convergent evolution of lophophores (in bryozoans and entoprocts versus brachiopods and phoronids) and of external two-part shell coverings (in brachiopods versus bivalve mollusks).

learning outcomes

You should be able to:

- Associate major morphological features of protostomes with the environment and life history of the respective organisms.
- Provide examples demonstrating how modifications of existing structures can lead to increases in species diversity.

1. How do flatworms survive without an internal transport system?
2. Why are most annelids restricted to moist environments?
3. Mollusks have evolved a great diversity of body plans. Provide some examples that demonstrate how the basic body organization of mollusks has been modified to yield this diversity.

The second of the two major protostome clades, the ecdysozoans, contains the vast majority of Earth's animal species. What evolutionary innovations led to this massive diversity?

***connect the concepts** The consequences of asexual reproduction, and the reasons that it

commonly leads to a buildup of deleterious mutations, are discussed in [Key Concept 20.5](#).

31.3 Ecdysozoans Grow by Shedding Their Cuticles

Many ecdysozoans are wormlike in form, although others—the arthropods, onychophorans, and tardigrades—have limbs. In this section we will look at the two clades of wormlike ecdysozoans: the priapulids, kinorhynchs, and loriciferans in one clade and the nematodes and horsehair worms in the other. [Key Concept 31.4](#) will be devoted to the most diverse ecdysozoans—the arthropods and their relatives—and the many forms their appendages take.

focus your learning

An exterior covering known as the cuticle is regularly shed as an ecdysozoan grows.

Nematodes are among the most abundant animals in many environments.

Although many nematodes are free-living, others are parasitic or predatory.

As we noted in [Key Concept 31.1](#), ecdysozoans can be identified by the presence of a body covering known as a cuticle, which provides these animals with both protection and support. The name of the group, Ecdysozoa, is derived from the Greek *ecdysis* (“to get out of”) plus *zoa* (“animals”). Periodic shedding of the cuticle is necessary so that ecdysozoans can grow. In many ecdysozoans that have wormlike bodies, the cuticle is relatively thin and flexible; it offers the animal some protection but provides only modest body support. A thin cuticle allows the exchange of gases, minerals, and water across the body surface, but it restricts the animal to moist habitats. Many species of ecdysozoans with thin cuticles live in marine sediments from which they obtain food, either by ingesting sediments and extracting organic material from them or by capturing larger prey using a toothed [pharynx](#) (a muscular organ at the anterior end of the digestive tract). Some freshwater species absorb nutrients directly through their thin cuticles, as do parasitic species that live within their hosts (endoparasites). Many wormlike ecdysozoans are predators, eating protists and small animals.

pharynx [Gk. throat] The part of the gut between the mouth and the esophagus.

Several marine ecdysozoan groups have relatively few species

Members of several species-poor groups of wormlike marine ecdysozoans—the priapulids, kinorhynchs, and loriciferans — have relatively thin cuticles that are molted periodically as the animals grow to full size. Embryos of a fossil species related to these ecdysozoans have been discovered in sediments laid down in China about 500 million years ago. This remarkable discovery shows that the ancestors of these animals developed directly from an egg to the adult form, as most of their modern descendants do.

The 20 known species of **priapulids** are cylindrical, unsegmented, wormlike animals with a three-part body plan consisting of a proboscis, trunk, and caudal appendage ("tail"). It should be clear from their appearance why they were named after the Greek fertility god Priapus ([Figure 31.15A](#)). Priapulids range in length from 0.5 millimeters to 20 centimeters. They live in burrows in fine marine sediments and prey on soft-bodied invertebrates such as polychaetes, which they capture with a toothed, muscular pharynx that they evert through the mouth and then withdraw into the body together with the grasped prey. Fertilization is external, and most species have a larval form that also lives in the mud.

(B) *Pycnophyes kielensis*

(C) *Nanaloricus mysticus*

Figure 31.15 Wormlike Marine Ecdysozoans Members of three ecdysozoan groups are marine bottom-dwellers. (A) Most priapulid species live in burrows on the ocean floor, extending the proboscis to feed. (B) Kinorhynchs are virtually microscopic. The cuticular plates that cover their bodies are molted periodically. (C) Six cuticular plates form a “corset” around the minute loriciferan body.

About 180 species of **kinorhynchs** have been described. They live in marine sands and muds and are virtually microscopic; no kinorhynchs are longer than 1 millimeter. Their bodies are divided into 13 segments, each covered with a separate cuticular plate ([Figure 31.15B](#)). These plates are periodically molted during growth. Kinorhynchs feed by ingesting sediments through a retractable proboscis (the group name means “movable snout”). They then digest the organic material found in the sediment, which may include living algae as well as dead matter. Kinorhynchs have no distinct larval stage; fertilized eggs develop directly into juveniles, which emerge from their egg cases with 11 of the 13 body segments already formed.

Loriciferans are also minute animals less than 1 millimeter long. They were not discovered until 1983. About 100 living species are known to exist, although only about 30 of these have been formally described to date. The body is divided into a head, neck, thorax, and abdomen and is covered by six plates, from which the loriciferans get their name (Latin *lorica*, “corset”). The plates around the base of the neck bear anterior-directed spines of unknown function ([Figure 31.15C](#)). Loriciferans live in coarse marine sediments. Little is known about what they eat, but some species apparently eat bacteria.

Nematodes and their relatives are abundant and diverse

Nematodes (roundworms) have a thick, multilayered cuticle that gives their unsegmented body its shape ([Figure 31.16](#)). As a nematode grows, it sheds its cuticle four times. Nematodes exchange oxygen and nutrients with their environment through both the cuticle and the gut wall, which is only one cell layer thick. Materials are moved through the gut by rhythmic contraction of a highly muscular pharynx. Nematodes move by contracting their longitudinal muscles.

Figure 31.16 Nematodes (A) The body plan of *Trichinella spiralis*, which causes trichinosis, is typical of parasitic nematodes. (B) This polarized light micrograph shows a cyst of *T. spiralis* in the muscle tissue of a host. (C) This free-living nematode lives in freshwater environments.

Nematodes are probably the most abundant and universally distributed of all animal groups. Many nematodes are microscopic; the largest known nematode, which reaches a length of 9 meters, is a parasite in the placentas of sperm whales. About 25,000 species have been described, but the actual number of living species may be more than 1 million. Countless nematodes live as scavengers in the upper layers of the soil, on the bottoms of lakes and streams, and in marine sediments. The topsoil of rich farmland may contain from 3 to 9 billion nematodes per acre. A single rotting apple may contain as many as 90,000 individuals.

One soil-inhabiting nematode, *Caenorhabditis elegans*, serves as a model organism in the laboratories of geneticists and developmental biologists. It is ideal for such research because it is easy to cultivate, matures in 3 days, and has a fixed number of body cells. Its genome has been completely sequenced.

Many nematodes are predators, feeding on protists and small animals (including other roundworms). Most significant to humans, however, are the many species that parasitize plants and animals. The nematodes that parasitize humans (causing serious diseases such as trichinosis and elephantiasis), domestic animals, and economically important plants have been studied intensively in an effort to find ways of controlling them.

The structure of parasitic nematodes is similar to that of free-living species, but the life cycles of many parasitic species have special stages that facilitate the transfer of individuals among hosts. *Trichinella spiralis*, the species that causes the human disease trichinosis, has a relatively simple life cycle. A person may become infected by eating the flesh of an animal (usually a pig) that has *Trichinella* larvae encysted in its muscles (see [Figure 31.16B](#)). The larvae are activated in the person's digestive tract, emerge from their cysts, and attach to the intestinal wall, where they feed. Later they bore through the intestinal wall and are carried in the bloodstream to muscles, where they form new cysts. If present in great numbers, these cysts can cause severe pain or death.

About 350 species of the unsegmented **horsehair worms** have been described. As their name implies, these animals are extremely thin in diameter; horsehair worms range from a few millimeters up to 1 meter in length. Most adult worms live in fresh water, among leaf litter and algal mats near the edges of streams and ponds. A few species live in damp soil.

Horsehair worm larvae are endoparasites of freshwater crayfishes and of terrestrial and aquatic insects ([Figure 31.17](#)). An adult horsehair worm has no mouth, and its gut is greatly reduced and probably nonfunctional. Some species may feed only as larvae, absorbing nutrients from their hosts across the body wall. But other species continue to shed their cuticles and grow after they have left their hosts, suggesting that adult worms may also absorb nutrients from their environment.

An adult **horsehair worm** leaves the body of the wood cricket it parasitized during its larval development.

Figure 31.17 Horsehair Worm Larvae Are Parasitic The larva of this horsehair worm (*Paragordius tricuspidatus*) can manipulate its host's behavior. The hatching worm causes the cricket to jump into water, where the worm emerges from the insect's body to continue its life cycle as a free-living adult. The cricket, having delivered its parasitic burden, drowns.

Priapulids, kinorhynchs, and loriciferans are relatively small, poorly known groups of wormlike marine ecdysozoans. Nematodes and horsehair worms have unsegmented wormlike bodies. Nematodes are among the most abundant and widely distributed animal groups.

learning outcomes

You should be able to:

- Compare cuticle thickness in the different ecdysozoans and explain the consequences of such variation.
 - Explain why the nematode *Caenorhabditis elegans* is a widely used model system in laboratory research.
 - Explain why nematode diversity is important to global ecosystems.
 - Provide examples of nematodes that are human parasites.
-

1. How and why does cuticle thickness vary among the ecdysozoans?
 2. Describe at least three ways in which nematodes have significant impacts on humans.
-

We will turn next to the animals that not only dominate the ecdyso-zoan clade but also constitute the most diverse group of animals on Earth.

31.4 Arthropods Are the Most Abundant and Diverse Group of Animals

Arthropods and their relatives are ecdysozoans with paired appendages. Arthropods are the most diverse group of animals in numbers of species (more than 1.2 million have been described, and many more remain to be discovered). Furthermore, the number of individual arthropods alive at any one time is estimated to be about 10^{18} , or 1 billion billion. Among the animals, only the nematodes are thought to exist in greater numbers.

focus your learning

Several key features have contributed to the success of arthropods.

Most pterygotes have two pairs of wings and go through complete or incomplete metamorphosis.

Insects started to diversify about 450 million years ago, about the same time as land plants first appeared.

Insects exchange gases via their tracheae.

Several key features have contributed to the success of the arthropods. As you have seen, their muscles are attached to the inside of their rigid exoskeletons. Their bodies are segmented, and each segment has muscles that operate that segment and the jointed appendages attached to it (see [Figure 31.4](#)). Jointed appendages permit complex movements, and different appendages are specialized for different functions. Encasement of the body within a rigid exoskeleton provides the animal with support for walking in the water or on dry land and provides some protection against predators. The waterproofing provided by chitin keeps the animal from dehydrating in dry air.

The four major arthropod groups living today are all species-rich: chelicerates (including the arachnids—spiders, scorpions, mites, and their relatives), myriapods (millipedes and centipedes), crustaceans (including shrimps, crabs, and barnacles), and hexapods (insects and their wingless relatives). The latter three groups are together known as mandibulates.

The jointed appendages of arthropods gave the clade its name, from the Greek words *arthron*, “joint,” and *podos*, “foot” or “limb.” Arthropods evolved from ancestors with simple, unjointed appendages. The exact forms of those ancestors are unknown, but some arthropod relatives with segmented bodies and unjointed appendages survive today. Before we describe the modern arthropods, we will discuss those arthropod relatives, as well as an early clade that went extinct but left an important fossil record.

Arthropod relatives have fleshy, unjointed appendages

The two living groups most closely related to the arthropods provide us with clues about the likely appearance of ancestral arthropod appendages. **Tardigrades** (water bears) have fleshy, unjointed legs and use their fluid-filled body cavities as hydrostatic skeletons ([Figure 31.18A](#)). Tardigrades are tiny (0.5-1.5 mm long) and lack both a circulatory system and gas exchange organs. The 1,200 known extant species live in marine sands and on temporary water films on plants. When these films dry out, the animals also lose water and shrink to small, barrel-shaped objects that can survive for at least a decade in a dormant state. Tardigrades have been found at densities as high as 2 million per square meter of moss.

Until fairly recently, biologists debated whether the **onychophorans** (velvet worms) were more closely related to annelids or to arthropods, but molecular evidence clearly links them to the latter. Indeed, with their soft, fleshy, unjointed, claw-bearing legs and elongate bodies, onychophorans may be similar in appearance to the ancestors of arthropods ([Figure 31.18B](#)). The 180 known species of onychophorans live in leaf litter in humid tropical environments. They have soft, segmented bodies that are covered by a thin, flexible cuticle that contains chitin. Like the tardigrades, they use their fluid-filled body cavities as hydrostatic skeletons. Fertilization is internal, and the large, yolky eggs are brooded within the body of the female.

(A) *Paramacrobiotus tonolli*

(B) *Peripatus* sp.

Figure 31.18 Arthropod Relatives with Unjointed Appendages (A) Tardigrades (water bears) can be abundant on the wet surfaces of mosses and plants and in temporary pools of water. (B) Onychophorans (velvet worms) have unjointed legs and use the body cavity as a hydrostatic skeleton. They are sometimes referred to as “living fossils,” meaning they are an ancient group that has changed very little over millennia.

Jointed appendages appeared in the trilobites

The **trilobites** flourished in Cambrian and Ordovician seas, but they disappeared in the great Permian extinction at the close of the Paleozoic era (251 million years ago). Because they had heavy exoskeletons that readily fossilized, they left behind an abundant record of their existence ([Figure 31.19](#)). About 10,000 species have been described.

Figure 31.19 A Trilobite Fossil The relatively simple, repetitive segments of the now-extinct trilobites are illustrated by a fossil trilobite from the shallow seas of the Ordovician period, some 450 million years ago.

The trilobites are the earliest known arthropods to have had jointed appendages. The body segmentation and appendages of trilobites followed a relatively simple, repetitive plan, but some of their appendages were modified for different functions. This specialization of appendages is a theme in the continuing evolution of the arthropods.

Chelicerates have pointed, nonchewing mouthparts

In the **chelicerates**, the head bears two pairs of pointed appendages modified to form mouthparts, called chelicerae, that are used to grasp (rather than chew) prey. Chelicerates typically have a two-part body plan, with anterior segments fused to form a cephalothorax, and rear segments fused to form an abdomen. In some groups, such as mites and ticks, there is no clear distinction between these two body parts. Most chelicerates have four pairs of walking legs. The 114,000 described species are grouped into three major clades: pycnogonids, horseshoe crabs, and arachnids.

The pycnogonids, or sea spiders, make up a poorly known group of about 1,000 marine species ([Figure 31.20A](#)). Most are small, with leg spans less than 1 centimeter, but some deep-sea species have leg spans up to 60 centimeters. A few pycnogonids eat algae, but most are carnivorous, eating a variety of small invertebrates.

(A) *Pseudopallene* sp.

(B) *Limulus polyphemus*

Figure 31.20 Two Small Chelicerate Groups (A) Although they are not spiders, it is easy to see how sea spiders got their common name. (B) A spawning aggregation of horseshoe crabs. Horseshoe crabs, like the onychophorans (see [Figure 31.18B](#)), are an example of "living fossils."

There are only four living species of horseshoe crabs, but many close relatives are known from fossils. Horseshoe crabs, which have changed very little morphologically over their long history, have a large horseshoe-shaped covering over most of the body. They are common in shallow waters along the eastern coast of North America and the southern and eastern coasts of Asia, where they scavenge and prey on bottom-dwelling animals. Periodically they crawl into the intertidal zone in large numbers to mate and lay eggs ([Figure 31.20B](#)).

Arachnids are abundant in terrestrial environments. Most arachnids have a simple life cycle in which miniature adults hatch from internally fertilized eggs and begin independent lives almost immediately. Some arachnids retain their eggs during development and give birth to live young.

The most species-rich and abundant arachnids are the spiders, scorpions, harvestmen, mites, and ticks ([Figure 31.21](#)). More than 60,000 described species of mites and ticks live in soil, leaf litter, mosses, and lichens, under bark, and as parasites of plants and animals. Mites are vectors for wheat and rye mosaic viruses; they cause mange in domestic animals and skin irritation in humans.

(A) *Simaetha* sp.

(B) *Androctonus* sp.

(C) *Leiobunum rotundum*

(D) *Trombidium* sp.

Figure 31.21 Arachnid Diversity (A) Jumping spiders are active, visually oriented, diurnal predators of insects. (B) Scorpions are nocturnal predators of small animals. (C) Harvestmen, also called daddy longlegs, are scavengers. (D) Mites include many free-living species as well as blood-sucking ectoparasites.

Spiders, of which about 50,000 species have been described, are important terrestrial predators with hollow chelicerae, which they use to inject venom into their prey. Some have excellent vision that enables them to chase and seize their prey. Others spin elaborate webs made of protein threads in which they snare prey. The threads are produced by modified abdominal appendages connected to internal glands that secrete the proteins, which solidify on contact with air. The webs of different groups of spiders are strikingly varied, and this variation enables the spiders to position their snares in many different environments for many different types of prey.

Mandibles and antennae characterize the remaining arthropod groups

The remaining three arthropod groups—the myriapods, crustaceans, and hexapods—have mouthparts that are mandibles, rather than chelicerae, so they are collectively called **mandibulates**. Mandibles can be used for chewing as well as for biting and holding food. Another distinctive characteristic of the mandibulates is the presence of sensory antennae on the head.

mandible A crushing part of arthropod mouth parts, in mammals, the lower jaw bone, in birds the upper or lower part of the beak.

MYRIAPODS The **myriapods** comprise the centipedes, millipedes, and their close relatives. Centipedes and millipedes have a well-formed head that bears the mandibles and antennae characteristic of mandibulates. Their distinguishing feature is a long, flexible, segmented trunk that bears many pairs of legs. Centipedes, which have one pair of legs per segment (**Figure 31.22A**), prey on insects and other small animals. In millipedes, two adjacent segments are fused so that each fused segment has two pairs of legs (**Figure 31.22B**). Millipedes scavenge and eat plants. More than 3,000 species of centipedes and 9,000 species of millipedes have been described; many more species probably remain unknown. Although most myriapods are less than a few centimeters long, some tropical species are ten times that size.

(A) *Scolopendra hardwickei*

(B) *Motyxia monica*

Figure 31.22 Myriapods (A) Centipedes have modified appendages that function as poisonous fangs for capturing active prey. They have one pair of legs per segment. (B) Millipedes are scavengers and plant eaters; they have smaller jaws and legs than centipedes do, and they have two pairs of legs per segment.

CRUSTACEANS

Crustaceans are the dominant marine arthropods today, and they are also common in fresh water and some terrestrial environments. The most familiar crustaceans are the shrimps, lobsters, crayfishes, and crabs (all decapods; [Figure 31.23A](#)) and the sow bugs (isopods; [Figure 31.23B](#)). Additional species-rich groups include the amphipods, ostracods, branchiopods ([Figure 31.23C](#)), and copepods ([Figure 31.23D](#)), all of which are found in freshwater and marine environments.

(C) *Triops longicaudatus*

(D) *Eudiaptomus gracilis*

(E) *Lepas* sp.

Figure 31.23 Crustacean Diversity (A) This decapod crustacean, a land crab, is found only on four islands in the South Atlantic Ocean. (B) This pillbug, a terrestrial isopod, can roll into a tight ball when threatened. (C) This tadpole shrimp, a branchiopod, is common in seasonal pools of the southwestern United States. (D) This minute copepod is found in freshwater lakes throughout Europe. (E) Gooseneck barnacles attach to a substrate by their muscular stalks and feed by protruding and retracting their feeding appendages.

Barnacles are unusual crustaceans that are sessile as adults ([Figure 31.23E](#)). Adult barnacles look more like mollusks than like other crustaceans, but as the zoologist Louis Agassiz remarked more than a century ago, a barnacle is "nothing more than a little shrimp-like animal, standing on its head in a limestone house and kicking food into its mouth."

 Media Clip 31.7 **Barnacles Feeding** www.Life11e.com/mc31.7

Most of the 67,000 described species of crustaceans have a body that is divided into three regions: head, thorax, and abdomen ([Figure 31.24](#)). The segments of the head are fused together, and the head bears five pairs of appendages. Each of the multiple thoracic and abdominal segments usually bears one pair of appendages. The appendages on different parts of the body are specialized for different functions, such as gas exchange, chewing, capturing food, sensing, walking, and swimming. In many species, a fold of the exoskeleton, the carapace, extends dorsally and laterally back from the head to cover and protect some of the other segments.

Figure 31.24 Crustacean Body Plan The bodies of crustaceans are divided into three regions: the head, thorax, and abdomen. Each body region bears specialized appendages. A shell-like carapace covers the head and thorax.

Q: In what ways is the crustacean body plan similar to and different from the insect body plan shown in [Figure 31.26](#)?

The fertilized eggs of most crustacean species are attached to the outside of the female's body, where they remain during their early development (see [Figure 31.23D](#)). At hatching, the young of some species are released as larvae; those of other species are released as juveniles that are similar in form to the adults. Still other species release eggs into the water or attach them to an object in the environment.

More than half of all described species are insects

During the Devonian period, more than 400 million years ago, some mandibulates colonized terrestrial environments. Of the several groups (including some crustacean isopods and decapods) that successfully colonized the land, none is more prominent today than the six-legged **hexapods**, which include the **insects** and their wingless relatives.

As you saw at the opening of this chapter, more than 1 million of the 1.8 million described living species on Earth are insects, but that is a small fraction of the number of species of insects that are thought to exist on Earth. One of Terry Erwin's experiments is shown in more detail in **Investigating Life: How Many Unknown Species?** This and similar experiments show that we have much to learn about the biodiversity of our own planet.

The wingless relatives of the insects—the springtails, two-pronged bristletails, and proturans—are probably the most similar of living forms to insect ancestors ([Figure 31.25](#)). These hexapods have a simple life cycle: they hatch from eggs as miniature adults. They differ from insects in having internal mouthparts. Springtails can be extremely abundant (up to 200,000 per m²) in soil, leaf litter, and on vegetation and are the most abundant hexapods in the world in terms of number of individuals (as opposed to number of species).

Figure 31.25 Wingless Hexapods The wingless hexapods, such as this springtail, have a simple life cycle. They hatch looking like miniature adults, then grow by successive molts of the cuticle.

Like crustaceans, insects have a body with three regions: head, thorax, and abdomen. They have a single pair of antennae on the head and three pairs of legs attached to the thorax. In most groups of insects, the thorax also bears two pairs of wings. Unlike other arthropods, insects have no appendages growing from their abdominal segments ([Figure 31.26](#)). Insects are distinguished from springtails and other hexapods by their external mouth-parts and by antennae that contain a motion-sensitive receptor called Johnston's organ. In addition, insects have a derived mechanism for gas exchange in air: a system of air sacs and tubular channels called tracheae (singular trachea) that extend from external openings called spiracles inward to tissues throughout the body (see [Figure 48.4](#)).

Figure 31.26 Insect Body Plan Like those of crustaceans, the bodies of insects are

divided into three regions: head, thorax, and abdomen. In insects, however, the thorax bears three pairs of legs and, in most groups, two pairs of wings. Unlike other arthropods, insects have no appendages growing from their abdominal segments.

How Many Unknown Species?

experiment

Original Papers: Erwin, T. L. 1988. The tropical forest canopy: The heart of biotic diversity. In E. O. Wilson, ed., *Biodiversity*, pp. 123–129. National Academy Press, Washington, D.C.

Erwin, T. L. 1997. Biodiversity at its utmost: Tropical forest beetles. In M. L. Reaka-Kudla, D. E. Wilson and E. O. Wilson, eds., *Biodiversity II*, pp. 27–40. Joseph Henry Press, Washington, D.C.

Entomologist Terry Erwin decided to estimate the number of undescribed species of insects. He devised and executed the following experiment in the forests of Panama.

QUESTION▶ How many species of insects exist on Earth?

METHOD

1. Use insecticide fog to collect all beetles from *Luehea seemannii* trees.
2. Sort beetles into species based on morphological differences.
3. Calculate the number of host-specific species (those restricted to *L. seemannii*) and the number of generalists.
4. Estimate the number of tree species per hectare of Panamanian forest.
5. Calculate the percent of tree-dwelling versus ground-dwelling beetles.
6. Calculate the percent of beetles among all insect species.
7. Use the calculations above to extrapolate the total number of insect species on Earth.

RESULTS

Erwin estimated that there are more than 30 million insect species on Earth, only about 1 million of which have been described.

CONCLUSION▶ Insect diversity is far greater than indicated by the known number of species, and the number of undescribed insect species far exceeds the total number of described species on Earth.

work with the data

The data in the table were used by entomologist Terry Erwin to estimate the undescribed diversity of insects. Review the design of Erwin's experiment above and in the opening story of this chapter. Then use Erwin's data to answer the questions.

Approximate number of beetle species collected from <i>Luehea seemannii</i> trees	1,200
Estimated number of host-specific beetles in this sample	163
Number of tree species per hectare of Panamanian forest	70
Percent of beetle species living in tree canopy (as opposed to ground-dwelling species)	75%
Percent of beetles among all insect species	40%

QUESTIONS▶

1. From the data in the table, estimate the number of insect species in an average hectare of Panamanian forest. Assume that the data for beetles on *L. seemannii* are representative of the other tree species, and that all the species of beetles that are *not* host-specific were collected in the original sample. Remember to sum your estimates of the number of (a) host-specific beetle species in the forest canopy; (b) non-host-specific beetle species in the forest canopy; (c) beetle species on the forest floor; and (d) species of all insects other than beetles.
2. There are about 50,000 species of tropical forest trees. Assume that the data for beetles on *L. seemannii* are representative of other species of tropical trees and calculate the number of host-specific beetles found on these trees. Add an estimated 1 million species of non-host-specific beetles that are expected across different species of trees (including those in temperate regions). Estimate the number of ground-dwelling beetle species based on the percentage used in Question 1. Now use this information to estimate the number of insect species on Earth, based on the percentage of beetles among all insect species.

A similar **work with the data** exercise may be assigned in **LaunchPad**.

[Table 31.2](#) lists the major insect groups. Two groups — the jumping bristletails and silverfish —are wingless and have simple life cycles, like the springtails and other non-insect hexapods. The remaining groups are all pterygote insects. **Pterygotes** have two pairs of wings, except in some groups in which one or both pairs of wings have been secondarily lost. These secondarily wingless groups include the parasitic lice and fleas, some beetles, and the worker individuals of many ant species.

table 31.2 The Major Insect Groups ^a	
Group	Approximate number of described living species
Jumping bristletails (Archaeognatha)	550
Silverfish (Zygentoma)	575
PTERYGOTE (WINGED) INSECTS (PTERYGOTA)	
Mayflies (Ephemeroptera)	3,250

Dragonflies and damselflies (Odonata)	6,000
Neopterans (Neoptera) ^b	
Ice-crawlers (Grylloblattodea)	35
Gladiators (Mantophasmatodea)	15
Stoneflies (Plecoptera)	3,800
Webspinners (Embioptera)	500
Angel insects (Zoraptera)	40
Earwigs (Dermaptera)	2,000
Grasshoppers and crickets (Orthoptera)	24,000
Stick insects (Phasmida)	3,000
Cockroaches (Blattodea)	4,500
Termites (Isoptera)	3,000
Mantids (Mantodea)	2,500
Booklice and barklice (Psocoptera)	5,750
Thrips (Thysanoptera)	6,000
Lice (Phthiraptera)	5,000
True bugs, cicadas, aphids, leafhoppers (Hemiptera)	104,000
Holometabolous neopterans (Holometabola)^c	
Ants, bees, wasps, sawflies (Hymenoptera)	150,000
Beetles (Coleoptera)	390,000
Strepsipterans (Strepsiptera)	650
Lacewings, ant lions, mantidflies (Neuroptera)	6,000
Dobsonflies, alderflies, fishflies (Megaloptera)	350
Snakeflies (Raphidioptera)	250
Scorpionflies (Mecoptera)	800
Fleas (Siphonaptera)	2,000
True flies (Diptera)	125,000
Caddisflies (Trichoptera)	12,000
Butterflies and moths (Lepidoptera)	180,000

^a The hexapod relatives of insects include the springtails (Collembola; 3,000 spp.), two-pronged bristletails (Diplura; 600 spp.), and proturans (Protura; 10 spp.). All are wingless and have internal mouthparts.

^b Neopteran insects can tuck their wings close to their bodies.

^c Holometabolous insects are neopterans that undergo complete metamorphosis.

Hatchling pterygotes do not look like adults; they undergo substantial changes at each molt. The immature stages of insects between molts are called **instars**. A substantial change that occurs between one developmental stage and another is called **metamorphosis**. If the changes between stages are gradual, an insect is said to have **incomplete metamorphosis**. If the change between at least some stages is dramatic, an insect is said to have **complete metamorphosis** (see [Figure 30.10](#)). In many insects with complete metamorphosis, different stages are specialized for different functions and use different food sources. In many species the larvae are specialized for feeding and growing, whereas the adults are specialized for reproduction and dispersal.

instar (in' star) An immature stage of an insect between molts.

metamorphosis (met' a mor' fo sis) [Gk. *meta*: between + *morphe*: form, shape] A change occurring between one developmental stage and another, as for example from a tadpole to a frog. (See complete metamorphosis, incomplete metamorphosis.)

incomplete metamorphosis Insect development in which changes between instars are gradual. (Contrast with direct development, complete metamorphosis.)

complete metamorphosis A change of state during the life cycle of an organism in which the body is almost completely rebuilt to produce an individual with a very different body form. Characteristic of insects such as butterflies, moths, beetles, ants, wasps, and flies.

Media Clip 31.8 **Complete Metamorphosis** www.Life11e.com/mc31.8

The adults of most flying insects have two pairs of stiff, membranous wings attached to the thorax. True flies, however, have one pair of wings and a pair of stabilizers called halteres (which are derived from the second pair of wings). In winged beetles, one pair of wings—the forewings—forms heavy, hardened wing covers.

Two groups of pterygotes, the mayflies and dragonflies ([Figure 31.27A](#)), cannot fold their wings against their bodies. This is the ancestral condition for pterygote insects, and the mayflies and dragonflies are not closely related to one another. Members of both groups have predatory or herbivorous aquatic larvae that transform into flying adults after they crawl out of the water. Dragonflies (and their relatives the damselflies) are active predators as adults. In contrast, adult mayflies lack functional digestive tracts. Adult mayflies live only about a day, just long enough to mate and lay eggs.

(A) *Libellula luctuosa*

(B) *Poekilocerus pictus*

(C) *Dysdercus* sp.

(D) *Hydropsyche* sp.

(E) *Chryschus cobaltinus*

(F) *Papilio machaon*

(G) *Delia* sp.

(H) *Polistes gallicus*

Figure 31.27 Diverse Pterygotes (A) Unlike most flying insects, a dragonfly cannot fold its wings over its back. (B) Orthopteran insects such as grasshoppers have incomplete metamorphosis: they undergo several molts, but the juvenile instars resemble small adults (incomplete metamorphosis). (C) Hemipterans such as this red cotton bug are known as "true" bugs. (D-H) Holometabolous insects undergo complete metamorphosis. (D) A larval caddisfly (bottom) emerges from its dark pupal case. (E) The beetles (Coleoptera) comprise the largest insect group; beetles such as this dogbane leaf beetle account for more than half of all holometabolous species. (F)

Butterflies and moths are the lepidopterans, whose phases of complete metamorphosis are familiar to many (see [Figure 30.10](#)). (G) Blowflies are among the "true" flies, the Dipterans. Adult blowflies feed on pollen or nectar, but lay their eggs on carrion, upon which the larvae feed. (H) These paper wasps are hymenopterans, a group in which most members display social behaviors.

All other pterygote insects—the **neopterans**—can tuck their wings out of the way upon landing and crawl into crevices and other tight places. Some neopteran groups undergo incomplete metamorphosis, so hatchlings of these insects are sufficiently similar in form to adults to be recognizable. Examples include the grasshoppers ([Figure 31.27B](#)), roaches, mantids, stick insects, termites, stoneflies, earwigs, thrips, true bugs ([Figure 31.27C](#)), aphids, cicadas, and leafhoppers. These groups acquire adult organ systems, such as wings and compound eyes, gradually through several juvenile instars.

More than 80 percent of all insects belong to a subgroup of the neopterans called the **holometabolous** insects (see [Table 31.2](#)), which undergo complete metamorphosis ([Figure 31.27D](#)). The many species of beetles account for almost half of this group ([Figure 31.27E](#)). Also included are lacewings and their relatives; caddisflies; butterflies and moths ([Figure 31.27F](#)); true flies ([Figure 31.27G](#)); and bees, wasps, and ants, some species of which display unique and highly specialized social behaviors ([Figure 31.27H](#)).

holometabolous Undergoing complete metamorphosis.

Molecular data suggest that insects began to diversify about 450 million years ago, about the time of the appearance of the first land plants. These early hexapods evolved in a terrestrial environment that lacked any other similar organisms, which in part accounts for their remarkable success. But the success of the insects is also due to their wings. Pterygote insects were the first animals in evolutionary history to achieve the ability to fly. Homologous genes control the development of insect wings and crustacean appendages, suggesting that the insect wing evolved from a dorsal branch of a crustacean-like limb ([Figure 31.28](#)). The dorsal limb branch of crustaceans is used for gas exchange. Thus the insect wing probably evolved from a gill-like structure that had a gas exchange function.

Figure 31.28 The Origin of Insect Wings? Insect wings may be derived from an ancestral appendage similar to that of modern crustaceans. (A) A diagram of the ancestral, multibranching arthropod limb. The uppermost dorsal branch may have been used for gas exchange. (B, C) The *pdm* gene, a Hox gene, is expressed throughout the dorsal limb segment of the thoracic limb of a crayfish (B) and in the wings of *Drosophila* (C).

Q: If the hypothesized origin of insect wings is correct, then what was a possible function of the structure that would become a wing in flying insects?

Flight opened up many new lifestyles and feeding opportunities that only the insects could exploit, such as pollination of (and coevolution with) flowering plants. Flight is almost certainly one of the reasons for the remarkable numbers of both insect species and individual insects, and for their unparalleled evolutionary success.

31.4 recap

All arthropods have segmented bodies. Muscles in each segment operate that segment and the appendages attached to it. Jointed, specialized appendages permit complex patterns of movement, including, in insects, the ability to fly. With flight, insects took advantage of new feeding and lifestyle opportunities, which contributed to the unparalleled evolutionary success of this group.

learning outcomes

You should be able to:

- Describe morphological innovations of arthropods, and their potential effects on arthropod diversity.
- Distinguish among different forms of metamorphosis in arthropods.
- Explain how the evolutionary innovations among arthropods are related to the distribution of major groups across the Earth's environments.

1. What features have contributed to making arthropods among the most abundant animals on Earth, both in number of species and in number of individuals?
2. Describe the difference between incomplete and complete metamorphosis.
3. There are more described and named species of insects than of all other species on Earth combined. However, only a very few insect species live in marine environments, and those species are restricted to the intertidal zone or the ocean surface. What factors may have contributed to the insects' lack of success in the oceans?

Key Features of Protostome Evolution

The protostomes encompass a staggering number of different body forms and lifestyles. The following aspects of protostome evolution have contributed to this enormous diversity:

The evolution of *segmentation* permitted some groups of protostomes to move different parts of the body independently of one another. Species in some groups gradually evolved the ability to move rapidly over and through the substrate, through water, and through air.

Complex life cycles with dramatic changes in form between one stage and another allow individuals of different stages to specialize on different resources.

Parasitism has evolved repeatedly, and many protostome groups parasitize plants and animals.

The evolution of *diverse feeding structures* allowed proto-stomes to specialize on many different food sources. Specialization on food sources undoubtedly contributed to reproductive isolation and further diversification.

Predation was a major selection pressure favoring the development of *hard external body coverings* (exoskeletons and shells). Such coverings evolved independently in many lophotrochozoan and ecdysozoan groups. In addition to providing protection, these coverings became key elements in the development of new systems of locomotion.

Better locomotion permitted prey to escape from predators, but also allowed predators to pursue their prey more effectively. Thus the evolution of animals has been, and continues to be, a complex "arms race" among predators and prey.

 Animation 31.1 **An Overview of the Protostomes** www.Life11e.com/a31.1

Many major evolutionary trends among the protostomes are shared by the deuterostomes, which include the chordates, the group to which humans belong. We will turn to the deuterostomes in the next chapter.

investigatinglife

Which groups of protostomes are thought to contain the most undiscovered species?

It is perhaps easier to list the groups of protostomes for which a nearly complete inventory of living species has been done than to list all the groups for which many new species remain to be de-scribed. Among the insects, the best-studied group, in terms of species, is the butterflies, which are widely collected and studied. There are still many species of other lepidopterans (such as moths), however, remaining to be discovered. As we explored in *Investigating Life: How Many Unknown Species?*, some other major insect groups, such as beetles, contain many undescribed species.

New species discovery and description rates remain high for al-most all other major groups of protostomes. Second to the insects, and perhaps even rivaling the insects in undiscovered diversity, are the nematodes. Although known nematode diversity is only about one-fortieth of known insect diversity (in terms of number of de-scribed species), the taxonomy of nematodes has been much more poorly studied than that of insects. Some biologists think there are likely to be species-specific parasitic nematodes specializing on most other species of multicellular organisms. If so, then there may be as many species of nematodes as there are of plants, fungi, and other animals combined.

Most of the other diverse groups of protostomes also contain many as yet undetected species, judging from the rate of new species descriptions. In particular, flatworms (especially the parasitic flukes and tapeworms), marine annelids, mollusks, crustaceans, myriapods, and chelicerates all contain large numbers of unde-scribed species.

Future directions

Biologists have now placed almost all known species into a comprehensive tree of life (see [Appendix A](#)). This achievement allows the development of new technology for automated species discovery and identification. Once we can identify an organism, it is then pos-sible to connect it to all the known information about that species. It should soon be possible to

construct a hand-held device that will isolate DNA from any sample, and then to sequence a series of target genes that can be used to place an unknown sample within the tree of life. This process results in either identification of a known species, or placement of an undescribed species with its closest relatives in the tree. This technology is expected to revolutionize the study of biodiversity and its applications.

► 31.1 Protostomes Account for More Than Half of All Described Species

- Protostomes ("mouth first") are bilaterally symmetrical animals with an anterior brain that surrounds the entrance to the digestive tract and a ventral nervous system. The embryonic blastopore of protostomes develops into a mouth.
- There are two major clades of protostomes, the lophotrochozoans and the ecdysozoans. **Review** [Figure 31.1](#), [Table 31.1](#), [Activities 31.1](#), [31.2](#)
- **Lophotrochozoans** include a wide variety of body forms. Within this group, lophophores (complex organs for both food collection and gas exchange), free-living trochophore larvae, and spiral cleavage evolved. Some of these features were subsequently lost in some lineages (or evolved convergently).
- Ecdysozoans have a body covering known as the cuticle, which they must molt in order to grow. Some ecdysozoans, especially the arthropods, have a rigid cuticle reinforced with chitin that functions as an exoskeleton. **Review** [Figure 31.4](#)
- Arrow worms may be most closely related to lophotrochozoans, or they may be the sister group of all other protostomes. Review [Figure 31.5](#)

► 31.2 Many Lophotrochozoans Have Ciliated Feeding Structures or Life Stages

- Lophotrochozoans range from animals with a blind gut and no internal transport system to animals with complete digestive tracts and complex internal transport systems. **Review** [Figure 31.6](#)
- Most species of bryozoans and entoprocts live in colonies produced through asexual reproduction. Individuals of both groups feed using a lophophore.
- Flatworms, rotifers, gastrotrichs, and their close relatives form a structurally diverse clade of ciliated lophotrochozoans. **Review** [Figure 31.7](#)
- Ribbon worms feed using a long, protrusible proboscis. **Review** [Figure 31.8](#)
- The shelled brachiopods and wormlike phoronids use a lophophore to feed; this lophophore may have evolved independently of the lophophore in bryozoans and entoprocts. **Review** [Figures 31.9](#), [31.10](#)
- Annelids are a diverse group of segmented worms that live in moist terrestrial and aquatic environments. **Review** [Figure 31.11](#)
- Mollusks underwent a dramatic evolutionary radiation based on a body plan consisting of three major components: a foot, a mantle, and a visceral mass. The four major living molluscan clades — chitons, bivalves, gastropods, and cephalopods—demonstrate the diversity that evolved from this three-part body plan. **Review** [Figure 31.13](#)

► 31.3 Ecdysozoans Grow by Shedding Their Cuticles

- Several species-poor groups of wormlike marine ecdysozoans—priapulids, kinorhynchans, and loriciferans—have thin cuticles.
- Nematodes have a thick, multilayered cuticle. Nematodes are among the most abundant

and universally distributed of all animal groups. **Review Figure 31.16**

- Horsehair worms are extremely thin; many are endoparasites as larvae.

► **31.4 Arthropods Are the Most Abundant and Diverse Group of Animals**

- One major ecdysozoan clade, the arthropods, has evolved jointed, paired appendages that have a wide diversity of functions. Collectively, arthropods are the dominant animals on Earth in number of described species.
- Encasement within a rigid exoskeleton provides arthropods with support for walking as well as some protection from predators. The waterproofing provided by chitin keeps arthropods from dehydrating in dry air.
- Jointed appendages permit complex movement patterns. Each arthropod segment has muscles attached to the inside of the exoskeleton that operate that segment and attached appendages.
- The onychophorans and the tardigrades are arthropod relatives that have simple, unjointed appendages. Trilobites, the first arthropods known to have had jointed appendages, disappeared in the Permian mass extinction.
- Chelicerates have a two-part body and pointed mouthparts that grasp prey; most chelicerates have four pairs of walking legs.
- Mandibles and antennae are synapomorphies of the mandibulates, which include the myriapods, crustaceans, and hexapods.
- The bodies of myriapods have two regions: a head with mandibles and antennae, and a segmented trunk that bears many pairs of legs.
- Crustaceans have segmented bodies that are divided into three regions—head, thorax, and abdomen—with different, specialized appendages in each region. **Review Figure 31.24**
- Hexapods—insects and their relatives—are the dominant terrestrial arthropods. They have the same three body regions as crustaceans, but no appendages form in their abdominal segments. **Review Figure 31.26, Table 31.2**
- Wings and the ability to fly first evolved among the pterygote insects, allowing them to exploit new lifestyles. **Review Figure 31.28**

See [Animation 31.1](#) for an overview of the protostomes.

Review

1.4 Insects exchange gases via their tracheae.

Original Papers: Braddy, S. J., M. Poschmann and O. E. Tetlie. 2008. Giant claw reveals the largest ever arthropod. *Biology Letters* 4: 106-109.

Kaiser A., C. J. Klok, J. J. Socha, W-K Lee, M. C. Quinlan and J. F. Harrison. 2007. Increase in tracheal investment with beetle size supports hypothesis of oxygen limitation on insect gigantism. *Proceedings of the National Academy of Sciences USA* 104: 13198-13203.

British scientists recently came upon something striking: a well-preserved fossil chelicera of a giant eurypterid sea scorpion dating back to the early Devonian period ([Figure A](#)). The claw belonged to the largest arthropod ever known on the planet, measuring nearly 2.5 meters in body length (longer than humans are tall). This new discovery was not the only representative of massive arthropods roaming Earth at that time; the Paleozoic fossil record is teeming with massive millipedes, monster cockroaches, and titanic trilobites. Why were these animals so large, and why don't we see supersized arthropods today?

Figure A

To find out, we must look back to life in the Paleozoic era, approximately 542-251 million years ago. During this time, seed plants invaded land, land vertebrates became abundant, and winged insects took to the skies for the first time. According to geologic estimates, atmospheric oxygen in the late Paleozoic made up 35 percent of the air, as compared with 21 percent today. [Chapter 24](#) described an experiment examining the relationship between atmospheric oxygen concentration and body size in fruit flies. Experimentally increasing O_2 concentrations resulted in fruit fly lineages that were significantly larger than control lineages, which lends support to the hypothesis that the increase in insect body size may have been due to higher oxygen concentrations. According to the fossil record, as O_2 concentrations declined at the end of the Permian period, so did the body size of arthropods.

Alexander Kaiser and his team wanted to know *why* oxygen might increase or limit growth. They knew that the larger an animal grows, the greater the distance required for oxygen to be transported to internal tissue. He thought that perhaps after a certain point the network of tracheae that supplies oxygen would start crowding other organs. To address this, the researchers compared mean values of tracheal density of the leg (TrD_{leg}) and the body (TrD_{tot}) against body length of living beetles from the literature, as shown in [Figure B](#). They then extrapolated upper limits (dashed horizontal lines) of tracheal density in beetles based on the probable density at which tracheae would start to crowd other tissues.

Figure B

Questions

1. Describe what is shown in the graph. Which is more limiting to the size of insects, the tracheal density of the leg or the tracheal density of the entire body? Explain your answer.
2. How do insects take in oxygen, and how does this compare with how humans and other vertebrates take in oxygen?
3. Based on the graph generated by Kaiser and his team, what size would you predict the largest living beetle could be today, given our current atmospheric oxygen levels? The largest living beetle is *Titanus giganteus*, which has a body length of approximately 17 cm. Does this fit your prediction?

Deuterostome Animals

Grass snake (*Natrix natrix*) with eggs. Shelled eggs facilitated the colonization of drier terrestrial environments by deuterostomes.

key concepts

- [2.1 Deuterostomes Include Echinoderms, Hemichordates, and Chordates](#)
- [2.2 Echinoderms and Hemichordates Are Restricted to Marine Environments](#)
- [2.3 Chordates Have a Dorsal Nerve Cord and a Notochord](#)
- [2.4 Life on Land Contributed to Vertebrate Diversification](#)
- [2.5 Humans Evolved among the Primates](#)

Which Came First, the Chicken or the Egg?

When people ponder the chicken and egg problem, it is supposedly a riddle without an answer. The first chicken must have hatched from an egg, but then didn't another chicken have to lay that egg? But if you understand evolutionary biology, then the answer to the question of whether the chicken or the egg came first is obvious, and it isn't even close. Shelled eggs originated hundreds of millions of years before the first chicken walked on Earth.

The lineage of birds that we now know as chickens is only a few million years old. If we followed that lineage back through time, the birds in it would look less like modern chickens with each preceding generation. But all birds lay shelled eggs (a phenomenon called oviparity, or "egg birth"), so we can logically infer that eggs existed long before the first chicken did. Birds are the only living group of dinosaurs, but fossil eggs for many groups of extinct dinosaurs have been discovered. The closest living relatives of birds are the crocodilians, and they also lay shelled eggs, as do turtles. Many (but not all) lizards and snakes also lay shelled eggs, and so do the earliest branching lineages of mammals, including the echidnas and duck-billed platypus. Other mammals modify the shelled egg into structures that allow the embryo to develop within the mother, so that the young are born after "hatching" inside the mother (viviparity, or "live birth").

By comparing reproductive biology across species, biologists can trace the origin of the shelled egg to the origin of amniotes. Amniotes include all living mammals and reptiles (including birds). The group derives its name from the amnion, one of four membranes that surround the embryo within the shelled egg of amniotes.

Most amphibians also lay eggs, but their eggs have no shell. The soft, jellylike coating of amphibian eggs can easily dry, threatening the developing embryo. So amphibian eggs need to be deposited in water, or at least in moist places where desiccation is not a problem. This limitation kept the earliest terrestrial tetrapods from fully exploiting drier terrestrial environments. The shelled egg was thus an important evolutionary innovation that resulted in a great terrestrial explosion of the amniotes.

QA What are the advantages and disadvantages of egg laying versus live birth?

32.1 Deuterostomes Include Echinoderms, Hemichordates, and Chordates

It may surprise you to learn that both you and a sea urchin are deuterostomes. Adult sea stars, sea urchins, and sea cucumbers—the most familiar echinoderms—look so different from adult vertebrates (fishes, frogs, lizards, birds, and mammals) that it may be difficult to believe all these animals are closely related. The evidence that all deuterostomes share a common ancestor that is not shared with the protostomes includes early developmental patterns and phylogenetic analysis of gene sequences, factors that are not apparent in the forms of the adult animals.

focus your learning

The best evidence that deuterostomes are a clade comes from phylogenetic analysis of gene sequences.

There are three major deuterostome clades: echinoderms, hemichordates, and chordates.

Deuterostomes share early developmental patterns

Historically, the deuterostomes were distinguished by three early developmental patterns:

- . Radial cleavage
- . Development of the blastopore into the anus and formation of the mouth at the opposite end of the embryo from the blastopore (the pattern that gives the deuterostomes their name)
- . Development of a coelom from mesodermal pockets that bud off from the cavity of the gastrula rather than by splitting of the mesoderm, as occurs among protostomes

These distinctions, however, are not the strongest evidence for the monophyly of the deuterostomes. Radial cleavage is not exclusive to deuterostomes, and it is now thought to be the ancestral condition for all bilaterians. In fact, some of the groups now known to be protostomes were once thought to be deuterostomes because their developmental patterns are similar to those of echinoderms and chordates. The development of the blastopore into an anus does characterize the deuterostomes, but it may be the ancestral condition for bilaterians rather than a derived feature of deuterostomes. Today the strongest support for the shared evolutionary relationships of the deuterostomes comes from phylogenetic analyses of DNA sequences of many different genes.

There are three major deuterostome clades

All deuterostomes are triploblastic, coelomate animals (see [Figure 30.6C](#)). Skeletal elements, where present, are internal rather than external. Some species have segmented bodies, but the segments are less obvious than those of annelids and arthropods. Although there are far fewer species of deuterostomes than of protostomes (see [Table 30.1](#)), we have a special interest in deuterostomes because we are members of that clade. The deuterostomes are also of interest because they include many large animals that strongly influence the characteristics of ecosystems. Many deuterostome species have been intensively studied in all fields of biology. Complex social behaviors are well developed among some deuterostomes (especially among the vertebrates).

The major groups of living deuterostomes comprise three distinct clades ([Figure 32.1](#)):

Figure 32.1 Phylogeny of the Deuterostomes The three principal groups of deuterostomes are the echinoderms, the hemichordates, and the chordates, which include the lancelets, tunicates, and vertebrates. The echinoderms and the vertebrates contain most of the described species.

 Activity 32.1 Deuterostome Phylogeny www.Life11e.com/ac32.1

- . **Echinoderms:** sea stars (starfish), sea urchins, and their relatives
- . **Hemichordates:** acorn worms and pterobranchs
- . **Chordates:** tunicates, lancelets, and vertebrates

In addition, some recent genomic analyses suggest that two poorly known groups, the xenoturbellids and the acoels, may also be deuterostomes, although the exact position of these groups among animals is controversial.

 Animation 32.1 An Overview of the Deuterostomes www.Life11e.com/a32.1

Fossils shed light on deuterostome ancestors

Scientists are learning much about the ancestors of modern deuterostomes from fossils discovered in 520-million-year-old rocks in China. Some of these early deuterostomes had skeletons similar to those of echinoderms, but unlike modern adult echinoderms, they had bilateral symmetry and a pharynx with slits through which water flowed. Another early deuterostome group, the yunnanozoans, was discovered in China's Yunnan Province. The well-preserved fossils reveal animals that had large mouths, six pairs of external gills, and a segmented posterior body section bearing a light cuticle ([Figure 32.2](#)). The features of these fossil animals, together with findings from phylogenetic analyses of living species, show that the earliest deuterostomes were bilaterally symmetrical, segmented animals with pharyngeal slits. The adult forms of the living echinoderms with their unique symmetry (in which the body parts are arranged along five radial axes) evolved much later. Other deuterostomes retained the

ancestral bilateral symmetry.

Yunnanozoon lividum

Figure 32.2 Ancestral Deuterostomes Had External Gills The extinct yunnanozoans may be ancestral deuterostomes. This fossil, which dates from the Cambrian, shows the six pairs of external gills and segmented posterior body that characterized these animals.

32.1 recap

The three major clades of deuterostomes are the echinoderms, the hemichordates, and the chordates. The common ancestry of these groups is supported by early developmental similarities and by phylogenetic analyses of DNA sequences.

learning outcomes

You should be able to:

- Summarize the developmental and molecular characteristics that distinguish deuterostomes.
 - Identify the major deuterostome clades and give examples of each.
1. What three developmental traits do all deuterostomes have in common? Why are some of these traits no longer considered to be strong evidence for the monophyly of deuterostomes?
 2. What evidence provides strong support for the mono-phyly of deuterostomes?
 3. What are the three major groups of deuterostomes? Place each of the following in the appropriate group: humans, acorn worms, rattlesnakes, tunas, and sea stars.

We will begin our survey of the deuterostomes with the echinoderms and hemichordates, the most distant of our relatives among the deuterostomes.

32.2 Echinoderms and Hemichordates Are Restricted to Marine Environments

About 13,000 species of echinoderms in 23 major groups have been described from their fossil remains. They are probably only a small fraction of the echinoderm species that have ever lived. Only 6 of the 23 major groups known from fossils are represented by species that survive today; many clades were lost during the periodic mass extinctions that have occurred throughout Earth's history. All of the 7,500 extant species of echinoderms and 120 species of hemichordates live in marine environments.

focus your learning

Echinoderms are bilaterally symmetrical as larvae but pentaradially symmetrical as adults.

Echinoderms use their tube feet in a variety of ways to capture prey.

Hemichordates have a bilaterally symmetrical, wormlike body organized into three major parts: a proboscis, a collar, and a trunk.

The echinoderms and hemichordates (together known as **ambu-lacrarians**) have a bilaterally symmetrical, ciliated larva ([Figure 32.3A](#)). Adult hemichordates are also bilaterally symmetrical. Echinoderms, however, undergo a radical change in form as they develop into adults ([Figure 32.3B](#)), changing from a bilaterally symmetrical larva into an adult with **pentaradial symmetry** (symmetry in five or multiples of five). As is typical of animals with radial symmetry, echinoderms have no head, and most species move equally well in many directions. Rather than having an anterior–posterior (head–tail) and dorsal–ventral (back–belly) body organization, most echinoderms have an **oral** side containing the mouth and an opposite **aboral** side containing the anus.

(A) Sea star larva
(bilateral symmetry)

(B) Adult sea star
(pentaradial symmetry)

Figure 32.3 Echinoderms Are Bilaterally Symmetrical as Larvae but Radially Symmetrical as Adults (A) The ciliated larva of a sea star has bilateral symmetry. Hemichordates have a similar larval form. **(B)** An adult sea star displays the pentaradial symmetry of adult echinoderms. The canals and tube feet of the water vascular system, as well as the calcified internal skeleton, are shown in this diagram. The body's orientation is oral–aboral rather than anterior–posterior.

pentaradial symmetry Symmetry in five or multiples of five; a feature of adult echinoderms.
oral [L. os: mouth] Pertaining to the mouth, or that part of the body that contains the mouth.

aboral The opposite side of the body from the mouth.

Some recent genomic analyses suggest that two groups of small, highly reduced, soft-bodied marine organisms, the xenoturbellids and the acoels, may be the sister group of the ambulacrarians, although other studies suggest that they are the sister group of bilaterians. The five known species of **xenoturbellids** are wormlike organisms up to 20 centimeters long that feed on or parasitize marine mollusks. They have a very simple body plan, with almost no well-defined organ systems. The mostly tiny (<2 millimeter) **acoels** are also highly reduced, wormlike organisms that live as plankton, between grains of sediment, or on other organisms such as corals ([Figure 32.4](#)). They are among the simplest of bilaterian animals, with no gut, circulatory system, respiratory system, or excretory system. They feed through a mouth and form a vacuole around tiny food items. They are hermaphrodites, and their sperm form between the epidermis and digestive structure. There are about 400 known species of acoels.

Wamionoa sp.

Figure 32.4 Highly Reduced Acoels May Be Relatives of the Ambulacrarians

Acoels (yellow) are seen here living on bubble coral (white). Acoels (“without coelom”) feed by enveloping food particles in a vacuole within which nutrients are digested. These hermaphroditic animals can reproduce rapidly and may become problematic in saltwater aquariums.

Echinoderms have unique structural features

In addition to pentaradial symmetry, adult echinoderms have two unique structural features. One is a system of calcified internal plates covered by thin layers of skin and some muscles. The calcified plates of most echinoderms are thick, and they fuse inside the entire body, forming an [internal skeleton](#). The other unique feature of this group is a [water vascular system](#), a network of water-filled canals leading to extensions called [tube feet](#) (see [Figure 32.3B](#)). This system functions in gas exchange, locomotion, and feeding. Seawater enters the system through a perforated structure called a madreporite. A calcified canal leads from the madreporite to the ring canal, which surrounds the esophagus (the tube leading from the mouth to the stomach). Radial canals branch off from the ring canal, extending through the arms (in species that have arms) and connecting with the tube feet. These structural innovations have been modified in many ways, resulting in a striking array of very different animals.

gas exchange, locomotion, and feeding.

tube feet A unique feature of echinoderms; extensions of the water vascular system, which functions in gas exchange, locomotion, and feeding.

Members of one major extant echinoderm clade, the crinoids (sea lilies and feather stars), were more abundant and species-rich 300–500 million years ago than they are today. There are some 80 described living sea lily species, most of which are sessile organisms attached to the substrate by a stalk. Feather stars ([Figure 32.5A](#)) grasp the substrate with specialized flexible appendages that allow for limited movement. About 600 living species of feather stars have been described.

(A) *Comanthina schlegeli*

(B) *Echinometra mathaei*

(C) *Bohadschia argus*

(D) *Marthasterias glacialis*

(E) *Ophiarachna incrassata*

Figure 32.5 Echinoderm Diversity (A) The flexible arms of this variable bushy feather star (a crinoid) are clearly visible. (B) Sea urchins are important grazers on algae in the intertidal zones of the world's oceans. (C) This sea cucumber has expelled a portion of its viscera as a sticky defense against a potential predator. (D) Sea stars are important predators on bivalve mollusks such as mussels and clams. Suction tips on its tube feet allow a sea star to grasp both shells of a bivalve and pull them open. (E) The arms of a brittle star are composed of hard but jointed plates.

Although some crinoids are sessile, most surviving echino—derms are motile. The two main groups of motile echinoderms are the echinozoans (sea urchins and sea cucumbers) and the asterozoans (sea stars and brittle stars). Sea urchins are hemispherical in shape and lack arms (Figure 32.5B). They are covered with spines that are attached to the underlying skeleton with ball-and-socket joints. These joints enable the spines to be moved so they can converge toward a point that has been touched. The spines, which vary among species in size and shape, can be

used for locomotion; a few produce toxic substances. They provide effective protection for the urchin, as many a scuba diver has found out the hard way. Sand dollars are flattened, disc-shaped relatives of sea urchins.

Sea cucumbers also lack arms, and their bodies are oriented in an atypical manner for an echinoderm ([Figure 32.5C](#)). The mouth is anterior and the anus is posterior (front and rear), in contrast to the oral—aboral (top and bottom) orientation of other echinoderms. Sea cucumbers can use most of their tube feet to move, but they use them primarily for attaching to the substrate.

Sea stars, popularly called starfish, are the most familiar echinoderms ([Figure 32.5D](#)). Their gonads and digestive organs are located in the arms, as seen in [Figure 32.3B](#). Their tube feet serve as organs of locomotion, gas exchange, and attachment. Each tube foot of a sea star consists of an internal ampulla connected by a muscular tube to an external suction cup that can stick to the substrate. The tube foot is moved by expansion and contraction of the circular and longitudinal muscles of the tube. Brittle stars are similar in structure to sea stars, but their flexible arms are composed of jointed, hard plates ([Figure 32.5E](#)), their gonads and viscera are contained in the central disk, and their tube feet lack suction cups or ampullae.

Echinoderms use their tube feet in a great variety of ways to capture prey. Sea lilies, for example, feed by orienting their arms in passing water currents. Food particles then strike and stick to the tube feet, which are covered with mucus-secreting glands. The tube feet transfer these particles to grooves in the arms, where ciliary action carries the food to the mouth.

Most sea urchins capture phytoplankton with their tube feet or scrape algae from rocks with a complex rasping structure. Sea cucumbers capture food with their anterior tube feet, which are modified into large, feathery, sticky tentacles that can be protruded from the mouth. Periodically a sea cucumber withdraws the tentacles, wipes off the material that has adhered to them, and digests it.

Many sea stars use their tube feet to capture large prey such as polychaetes, gastropod and bivalve mollusks, small crustaceans such as crabs, and fishes. With hundreds of tube feet acting simultaneously, a sea star can grasp a bivalve in its arms, anchor the arms with its tube feet, and by steady contraction of the muscles in its arms, gradually exhaust the muscles the bivalve uses to keep its shell closed (see [Figure 32.5D](#)). To feed on the bivalve, the sea star can push its stomach out through its mouth and then through the narrow space between the two halves of the bivalve's shell. The sea star's stomach then secretes enzymes that digest the prey.

Media Clip 32.1 **Sea Star Hunting Bivalves** www.Life11e.com/mc32.1

Most of the 2,000 species of brittle stars ingest particles from the upper layers of sediments and assimilate the organic material from them, although some species filter suspended food particles from the water, and others capture small animals.

Hemichordates are wormlike marine deuterostomes

Hemichordates—acorn worms and ptero-branches—have a bilaterally symmetrical, wormlike body organized in three major parts: a proboscis, a collar (which bears the mouth), and a trunk (which contains the other body parts). The 90 known species of acorn worms range up to 2 meters long ([Figure 32.6A](#)). They live in burrows in muddy and sandy marine sediments. The digestive tract of an acorn worm consists of a mouth behind which are a muscular pharynx and an intestine. The pharynx opens to the outside through several pharyngeal slits through which water can exit. Highly vascularized tissue surrounding the pharyngeal slits serves as a gas exchange apparatus. Acorn worms respire by pumping water into the mouth and out through the pharyngeal slits. They capture prey with the large proboscis, which is coated with sticky mucus to which small organisms in the sediment stick. The mucus and its attached prey are conveyed by cilia to the mouth. In the esophagus, the food-laden mucus is compacted into a ropelike mass that is moved through the digestive tract by ciliary action.

(A) *Saccoglossus kowalevskii*

(B)

Figure 32.6 Hemichordates (A) The proboscis of an acorn worm is modified for burrowing. (B) Some pterobranch species form colonies.

The 30 living species of pterobranchs are sedentary marine animals up to 12 millimeters long that live in a tube secreted by the proboscis. Some species are solitary; others form colonies of individuals joined together ([Figure 32.6B](#)). Behind the proboscis is a collar with anywhere from one to nine pairs of arms. The arms bear long tentacles that capture prey and function in gas exchange.

32.2 recap

Adult echinoderms are characterized by pentaradial symmetry, an internal skeleton of calcified plates, and a unique water vascular system. Hemichordates have a bilaterally symmetrical body divided into three parts: proboscis, collar, and trunk. Both groups are restricted to marine environments.

learning outcomes

You should be able to:

- Compare the body plans of larval and adult echinoderms.
- Summarize the ways that various echinoderms use their tube feet to feed.
- Contrast the ways that echinoderms and hemichordates feed.

1. How does the body form of echinoderm larvae differ from that of echinoderm adults?
2. Describe some of the ways that echinoderms use their tube feet to obtain food, and contrast this with the feeding mechanism of hemichordates.

Having described the deuterostome groups that are most distantly related to us, we will next turn our attention to the unique features that evolved in the chordates, a clade dominated by the vertebrates.

32.3 Chordates Have a Dorsal Nerve Cord and a Notochord

As you have seen, it is not obvious from examining adult animals that echinoderms and chordates share a common ancestor. The evolutionary relationships among some chordate groups are not immediately apparent either. The features that reveal all of these evolutionary relationships are seen primarily in the larvae—in other words, it is during the early developmental stages that these evolutionary relationships are evident.

focus your learning

Chordates are characterized by a dorsal hollow nerve cord, a post-anal tail, and a dorsal supporting rod called a notochord.

Vertebrates are distinguished by an additional dorsal supporting structure—the vertebral column—and other features.

Hagfishes have weak circulatory systems and lack, or have reductions in, many otherwise shared vertebrate features.

Lampreys and hagfishes may look superficially similar, but they differ greatly in their biology. Ray-finned fishes evolved swim bladders, which are organs of buoyancy.

There are three principal chordate clades: the **lancelets** (also called cephalochordates), the **tunicates** (also called urochordates), and the **vertebrates** (see [Figure 32.1](#)). Adult chordates vary greatly in form, but all chordates display the following derived structures at some stage in their development ([Figure 32.7](#)):

Figure 32.7 Key Features May Be Most Apparent in Early Development (A) The tunicate larva (but not the adult) has all three key features of chordates: a dorsal hollow nerve cord, a post-anal tail, and a notochord. **(B)** All three chordate synapomorphies are retained in the adult lancelet.

A dorsal hollow nerve cord

A tail that extends beyond the anus

A dorsal supporting rod, the notochord

The **notochord** is the most distinctive derived chordate trait. It is composed of a core of large cells with turgid fluid-filled vacuoles, which make it rigid but flexible. In the tunicates the notochord is lost during metamorphosis to the adult stage. In most vertebrate species it is replaced during development by skeletal structures that provide support for the body.

notochord (no' tow kord) [Gk. *notos*: back + *chorde*: string] A flexible rod of gelatinous material serving as a support in the embryos of all chordates and in the adults of tunicates and lancelets.

The pharyngeal slits found in the common ancestor of deuterostomes are present at some developmental stage in all chordates but are often lost or greatly modified in adults. In chordates, the pharyngeal slits are separated and supported by structural elements called pharyngeal arches. In tunicates and lancelets, the pharynx functions as a straining device to filter small food particles. In fishes and larval amphibians, some of the pharyngeal arches develop into gill arches, which support the respiratory gills and are often used as feeding

structures as well. Developmentally, some pharyngeal arches also develop into elements of the vertebrate jaw, as well as parts of the tongue, larynx, trachea, and middle ear of tetrapods (four-legged vertebrates). Some of the pharyngeal slits are modified in tetrapods to form the eustachian tube and middle ear chamber.

Adults of most lancelets and tunicates are sedentary

The 35 species of lancelets are small animals that rarely exceed 5 centimeters in length. The notochord, which provides body support, extends the entire length of the body throughout the animal's life (see [Figure 32.7B](#)). Lancelets are found in shallow marine and brackish waters worldwide. Most of the time they lie covered in sand with their head protruding above the sediment, but they can swim. The pharynx has been enlarged and modified to form a structure called a pharyngeal basket, with which the lancelet filters prey from the water. During the reproductive season, the gonads of males and females enlarge greatly. At spawning, the walls of the gonads rupture, releasing eggs and sperm into the water column, where fertilization takes place.

All members of the three major tunicate groups—the sea squirts (also called ascidians), thaliaceans, and larvaceans—are marine animals. More than 90 percent of the 2,800 known species of tunicates are sea squirts. Individual sea squirts range in length from less than 1 millimeter to 60 centimeters. Some sea squirts form colonies by asexual budding from a single founder. Colonies may measure several meters across. The baglike body of an adult sea squirt is enclosed in a tough tunic, which is the basis for the name “tunicate” ([Figure 32.8A](#)). The tunic is composed of proteins and a complex polysaccharide secreted by epidermal cells. The sea squirt pharynx is enlarged into a pharyngeal basket that filters prey from the water passing through it.

(A) *Clavelina dellavallei*

(B) *Pegea* sp.

Figure 32.8 Adult Tunicates (A) The transparent tunic and the pharyngeal basket are clearly visible in this sea squirt. (B) A chainlike colony of thaliaceans (salps) floats in tropical waters.

In addition to its pharyngeal slits, a sea squirt larva has a dorsal hollow nerve cord and a notochord that is restricted mostly to the tail region (see [Figure 32.7A](#)). Bands of muscle surround the notochord, which provide support for the body. After a short time swimming in the plankton, the larvae of most species settle on the seafloor and transform into sessile adults. The swimming, tadpolelike larvae suggest a close evolutionary relationship between tunicates and vertebrates (see [Figure 21.6](#)).

Thaliaceans (salps and their relatives) are tunicates that can live singly or in chainlike colonies up to several meters long ([Figure 32.8B](#)). They float in tropical and subtropical oceans at depths down to 1,500 meters. Larvaceans are solitary planktonic animals that retain the notochord and dorsal hollow nerve cord throughout their lives. Most larvaceans are less than 5 millimeters long, but some species that live near the bottom of deep ocean waters build delicate casings of mucus that may be more than a meter wide. They snare sinking organic particles (their primary food source) with elaborate filters built into their mucus “houses.” When the old “house” gets clogged with excess debris, the animal builds a new one.

A dorsal supporting structure replaces the notochord in vertebrates

In one chordate group, the vertebrates, a new dorsal supporting structure evolved. This group takes its name from the jointed, dorsal [vertebral column](#) that typically replaces the notochord during early development as the primary supporting structure. The individual elements in the vertebral column are called vertebrae. Four other key features characterize the vertebrates as well ([Figure 32.9](#)):

Figure 32.9 The Vertebrate Body Plan A ray-finned fish is used here to illustrate some of the structural elements common to all vertebrates. In addition to the paired pelvic fins, these fishes have paired pectoral fins on the sides of their bodies (not seen in this cutaway view).

vertebral column [L. *vertere*: to turn] The jointed, dorsal column that is the primary support structure of vertebrates.

An anterior *skull* enclosing a large brain

A rigid internal *skeleton* supported by the vertebral column

Internal organs *suspended in a coelom*

A well-developed *circulatory system*, driven by contractions of a ventral *heart*.

These structural features can support large, active animals. The internal skeleton provides support for an extensive muscular system, which receives oxygen from the circulatory system and is controlled by the central nervous system. The evolution of these features allowed many vertebrates to become large, active predators, which in turn allowed the vertebrates to diversify widely ([Figure 32.10](#)).

Figure 32.10 Phylogeny of the Living Vertebrates This phylogenetic tree shows the evolution of some of the key innovations among the major groups of vertebrates.

All of the nonvertebrate deuterostomes live in marine environments. The lineage that led to the vertebrates is also thought to have evolved in the oceans, although probably in an estuarine environment (where fresh water meets salt water). The first vertebrates appeared in the Cambrian; since then they have radiated into marine, freshwater, terrestrial, and aerial environments worldwide. There are about 65,000 species of living vertebrates.

The phylogenetic relationships of jawless fishes are uncertain

The **hagfishes** are thought by many to be the sister group to the remaining vertebrates (see [Figure 32.10](#)). Hagfishes ([Figure 32.11A](#)) have a weak circulatory system with three small accessory hearts (rather than a single, large heart); a partial cranium, or skull (containing a brain with no cerebrum or cerebellum, two main regions that characterize the brains of other vertebrates); and no jaws or stomach. They also lack separate, jointed vertebrae and have a skeleton composed of a firm but pliable material called cartilage. Thus some biologists do not consider hagfishes to be vertebrates and instead use the term “craniates” to refer collectively to the hagfishes and the vertebrates. Some analyses of gene sequences suggest, however, that hagfishes may be the sister group of the **lampreys** ([Figure 32.11B](#)); in this phylogenetic arrangement, the hagfishes and the lampreys are collectively called the cyclostomes (“circle mouths”). If in fact the hagfishes and lampreys do form a monophyletic group, then hagfishes must have secondarily lost many of the major vertebrate morphological features during their evolution.

(A) *Eptatretus stoutii*

(B) *Lampreta fluviatilis*

Figure 32.11 Modern Jawless Fishes (A) Hagfishes burrow in the ocean mud, from which they extract small prey. They also scavenge on dead or dying fishes. Hagfishes have degenerate eyes, which has led to their being called (inaccurately) “blind eels.” (B) Many species of lampreys are ectoparasites that attach to the bodies of living fishes and use their large, jawless mouth to suck blood and flesh. This species lives in freshwater rivers, but some lampreys can live in marine environments.

The 80 known species of hagfishes are unusual marine animals that produce copious quantities of mucus as a defense. They are virtually blind and rely largely on the four pairs of sensory tentacles around the mouth to detect food. Although they have no jaws, hagfishes have a tonguelike structure equipped with toothlike rasps that they use to tear apart dead organisms and to capture their principal prey, polychaete worms. Hagfishes have direct development (no larvae), and individuals may actually change sex from year to year (from male to female and

vice versa).

Media Clip 32.2 Hagfish Slime www.Life11e.com/mc32.2

Although the lampreys and hagfishes may look superficially similar (with elongate eel-like bodies and no paired fins), they differ greatly in their biology. Lampreys have a complete skull and distinct and separate (although rudimentary) vertebrae, all cartilaginous rather than bony. Lampreys undergo a complete metamorphosis from filter-feeding larvae, known as ammocoetes, which are morphologically similar to adult lancelets. The adults of many species of lampreys are parasitic, although several lineages of lampreys evolved to become nonfeeding as adults. These nonfeeding adults survive for only a few weeks after metamorphosis—just long enough to breed. In the species that are parasitic as adults, the round mouth is a rasping and sucking organ that is used to attach to prey and rasp at the flesh (see [Figure 32.11B](#)).

The nearly 50 species of lampreys either live permanently in fresh water or are anadromous—meaning they live in coastal salt water and move into fresh water to breed. Some species of lampreys are critically endangered because of recent habitat changes and losses.

Jaws and teeth improved feeding efficiency

Many kinds of jawless fishes were found in the seas, estuaries, and fresh waters of the Ordovician, Silurian, and Devonian periods, but hagfishes and lampreys are the only jawless fishes that survived beyond the Devonian. Late in the Ordovician, some fishes evolved jaws via modifications of the skeletal arches that supported the gills ([Figure 32.12A](#)). Those fishes and their descendants are referred to as **gnathostomes** (Greek, “jaw mouths”). Jaws greatly improved feeding efficiency, as an animal with jaws can grasp, subdue, and swallow large prey. Jawed fishes rapidly diversified during the Devonian period, eventually replacing the jawless fishes in dominance of the seas.

(B)

Figure 32.12 Jaws and Teeth Increased Feeding Efficiency(A) These diagrams illustrate one probable scenario for the evolution of jaws from the anterior gill arches of jawless fishes. **(B)** Jaws of the extinct giant shark *Carcharodon megalodon* display the teeth that indicate an extreme predatory lifestyle.

The earliest jaws were simple, but the evolution of teeth made feeding even more efficient ([Figure 32.12B](#)). In predators, teeth function crucially both in grasping and in breaking up prey. In both predators and herbivores, teeth enable an animal to chew both soft and hard body parts of their food organisms. Chewing also aids chemical digestion and improves an animal's ability to extract nutrients from its food. Vertebrates are remarkable in the diversity of their jaws and teeth, and in their physiological adaptations for *digestion of a wide variety of food items.

Fins and swim bladders improved stability and control over locomotion

Most jawed fishes have a pair of pectoral fins just behind the gill slits and a pair of pelvic fins anterior to the anus (see [Figures 32.9](#) and [32.13A](#)). These paired fins stabilize the fish's position in water (and in some cases, help propel it). Median dorsal and anal fins also stabilize the fish, or may be used for propulsion in some species. In many fishes, the caudal (tail) fin helps propel the animal and enables it to turn rapidly.

Several groups of jawed fishes became abundant during the Devonian. Among them were the **chondrichthyans**—sharks, skates, and rays (about 1,000 living species) and chimaeras (40 living species). Like hagfishes and lampreys, these fishes have a skeleton composed entirely of cartilage. Their skin is flexible and leathery, sometimes bearing scales that give it the consistency of sandpaper. Sharks move forward by means of lateral (side-to-side) undulations of the body and caudal fin ([Figure 32.13A](#)). Skates and rays propel themselves by means of vertical undulating movements of their greatly enlarged pectoral fins ([Figure 32.13B](#)).

Figure 32.13 Chondrichthyans (A) Most sharks are active marine predators, as

epitomized by the great white shark seen here. **(B)** Skates and rays, represented here by a blue spotted fantail ray, feed on the ocean bottom. Their modified pectoral fins are used for propulsion; their other fins are greatly reduced. **(C)** A chimaera, or ratfish. Many of these deep-sea fishes possess modified dorsal fins that contain toxins.

Most sharks are predators, but some feed by straining plankton from the water. Most skates and rays live on the ocean floor, where they feed on mollusks and other animals buried in the sediments. Nearly all chondrichthyans live in the oceans, but a few are estuarine or migrate into lakes and rivers. One group of stingrays is found in river systems of South America. The less familiar chimaeras ([Figure 32.13C](#)) live in deep—sea or cold waters.

One lineage of aquatic gnathostomes gave rise to the bony vertebrates, which soon split into two main lineages—the **ray—finned fishes** and the **lobe—limbed vertebrates**. Bony vertebrates have internal skeletons of calcified, rigid bone rather than flexible cartilage. In early bony vertebrates, gas—filled sacs supplemented the gas exchange function of the gills by giving the animals access to atmospheric oxygen. These features enabled these fishes to live where oxygen was periodically in short supply, as it often is in freshwater environments. In the ray—finned fishes, these lunglike sacs evolved into [swim bladders](#), which are organs of buoyancy. By adjusting the amount of gas in its swim bladder, ray—finned fishes can control the depth at which it remains suspended in the water while expending very little energy to maintain its position.

swim bladder An organ used primarily to regulate buoyancy in fish.

The outer body surface of most species of ray—finned fishes is covered with thin, flat, lightweight scales that provide protection or enhance movement through the water. The gills open into a single chamber covered by a hard flap, called an operculum. Movement of the operculum increases the flow of water over the gills, where gas exchange takes place.

Ray—finned fishes began to diversify during the Mesozoic era and continued to radiate extensively throughout the Tertiary period. Today there are about 32,000 known living species, encompassing a remarkable variety of sizes, shapes, and lifestyles ([Figure 32.14](#)). The smallest are less than 1 centimeter long; the largest weigh as much as 900 kilograms. Ray—finned fishes exploit nearly all types of aquatic food sources. In the oceans they filter plankton from the water, rasp algae from rocks, eat corals and other soft—bodied colonial animals, dig animals from soft sediments, and prey on virtually all kinds of other fishes. In fresh water they eat plankton, devour insects, eat fruits that fall into the water, and prey on other aquatic vertebrates and, occasionally, terrestrial vertebrates. Many ray-finned fishes are solitary, but in open water others form large aggregations called schools. Many species perform complicated behaviors to maintain schools, build nests, court mates, and care for their young.

(A) *Pygoplites diacanthus*

(B) *Phyllopteryx taeniolatus*

(C) *Ostracion meleagris*

(D) *Edriolychnus schmidtii*

Figure 32.14 Diversity among the Ray-Finned Fishes (A) The brightly colored regal angelfish lives around Indo—Pacific coral reefs. Its deep, laterally compressed body and enlarged dorsal and anal fins increase its apparent size. (B) This slow—moving weedy seadragon relies on its highly modified body and fins to provide camouflage in swaying seaweed. (C) This spotted boxfish is a member of another large ray—fin clade, the serranids, which also includes the sea basses and groupers. (D) Deep—sea anglerfishes live below the level of light penetration. The large fish shown here is a female; the two smaller fishes are males, which fuse to the female for life.

Although ray—finned fishes can readily control their position in open water using their fins and swim bladder, their eggs tend to sink. Some species produce small eggs that are buoyant enough to complete their development in open water, but many marine fishes move to food—rich shallow waters to lay their eggs. That is why coastal waters and estuaries are so important in the life cycles of many marine fishes. Some ray—finned fishes, such as salmon, are anadromous, moving from the ocean to the fresh waters in which they breed.

32.3 recap

Chordates are characterized by a dorsal hollow nerve chord, a post—anal tail, and a dorsal supporting rod called a notochord at some point during the life cycle. Specialized structures for support (a vertebral column), locomotion (such as fins), and feeding (jaws and teeth) evolved among aquatic vertebrates.

learning outcomes

You should be able to:

- Recognize chordates and vertebrates, and distinguish them from other animals.
- Use examples to assess whether hagfishes should be considered vertebrates.
- Compare and contrast hagfishes and lampreys.
- Describe the modifications and losses of appendages in different lineages of vertebrates and how these modifications are related to function.

1. Describe the synapomorphies that characterize the chordates and the vertebrates, respectively.
2. How do the hagfishes differ from the lampreys in morphology? Why do some biologists

contend that hagfishes are not vertebrates?

3. The body plan of most vertebrates is based on four appendages. What are the varied forms that these appendages take, and how are they used? In which lineages have two or more of these appendages been lost?

In the lobe—limbed vertebrates, the gas—filled sacs that gave rise to swim bladders in ray—finned fishes became specialized for another purpose: breathing air. That adaptation set the stage for the vertebrates to move onto the land.

***connect the concepts** The many physiological adaptations of vertebrates for digesting plants and animals are described in detail in [Chapter 50](#).

32.4 Life on Land Contributed to Vertebrate Diversification

The evolution of lunglike sacs in fishes set the stage for the vertebrate invasion of the land. Some early ray—finned fishes probably used those sacs to supplement their gills when oxygen levels in the water were low, as many groups of ray—finned fishes do today. But with their unjointed fins, those fishes could only flop around when out of water. Changes in the structure of the fins first allowed lobe—limbed vertebrates to support themselves better in shallow water, and later, to move better on land.

focus your learning

Most modern amphibians are confined to moist environments because they rapidly lose water when their skin is exposed to air.

Birds are a specialized group of theropods and are the only group of dinosaurs to survive the mass extinction event at the end of the Cretaceous.

Feathers are modified scales, which probably evolved first for insulation and then for flight.

Mammals increased dramatically in number, diversity, and size after non—avian dinosaurs disappeared during the mass extinction at the end of the Cretaceous.

Mammals are distinguished by having sweat glands, mammary glands, hair, and a four—chambered heart.

Movements of the continents affected the diversification of eutherians.

Modifications of the amniote egg allowed the embryo to develop inside its mother's body.

Jointed limbs enhanced support and locomotion on land

In the lobe—limbed vertebrates, the paired pelvic and pectoral fins developed into more muscular fins that were joined to the body by a single enlarged bone. The modern representatives of these lobe—limbed vertebrates include the coelacanth, lungfishes, and tetrapods.

The coelacanth flourished from the Devonian until about 65 million years ago, when they were thought to have become extinct. But in 1938 a commercial fisherman caught a living coelacanth off South Africa. Since that time, hundreds of individuals of this extraordinary fish, *Latimeria chalumnae*, have been collected ([Figure 32.15A](#)). A second species, *L. menadoensis*, was discovered in 1998 off the Indonesian island of Sulawesi. *Latimeria*, a predator of other fishes, reaches a length of about 1.8 meters and weighs up to 82 kilograms. Its skeleton is composed mostly of cartilage, not bone. The cartilaginous skeleton is a derived feature in this

clade because it had bony ancestors.

(A) *Latimeria chalumnae*

(B) *Protopterus annectens*

(C) *Tiktaalik roseae*

Figure 32.15 The Closest Relatives of Tetrapods (A) The African coelacanth, discovered in deep waters of the Indian Ocean off the South African coast, represents one of two surviving species of a group that was once thought to be extinct. (B) All surviving lungfish species, such as this African lungfish, live in the Southern

Hemisphere. **(C)** *Tiktaalik*, a fossil lobe—limbed vertebrate from the Devonian, is believed to represent a transitional species intermediate between the finned fishes and the limbed tetrapods.

Media Clip 32.3 **Coelacanth**s in the Deep Seas www.Life11e.com/mc32.3

Lungfishes were important predators in shallow—water habitats in the Devonian, but most lineages died out. The six surviving species live in stagnant swamps and muddy waters in South America, Africa, and Australia ([Figure 32.15B](#)). Lungfishes have lungs derived from the lunglike sacs of their ancestors as well as gills. When ponds dry up, individuals of most species can burrow deep into the mud and survive for many months in an inactive state while breathing air.

It is believed that some early aquatic lobe—limbed vertebrates began to use terrestrial food sources, became more fully adapted to life on land, and eventually evolved to become ancestral **tetrapods** (“four legs”). How was this transition from an animal that swam in water to one that walked on land accomplished? Early in 2006, scientists reported the discovery of a Devonian fossil lobe-limbed vertebrate, since then named *Tiktaalik*, which possessed intermediate appendages between the fins of fishes and the limbs of terrestrial tetrapods ([Figure 32.15C](#)). It appears that limbs capable of propping up a large fish and making the front—to—rear movements necessary for walking evolved while these animals still lived in water. These limbs appear to have functioned in holding the animals upright in shallow water, perhaps even allowing them to hold their head above the water’s surface. These same structures were then co—opted for movement on land, at first probably for foraging on brief trips out of water.

Among the lobe—limbed vertebrates, limbs capable of movement on land evolved from the short, muscular fins of aquatic ancestors ([Figure 32.16](#)). The resulting four terrestrial limbs give the tetrapods their name. The basic skeletal elements of those limbs can be traced through major changes in limb form and function among the terrestrial vertebrates.

Figure 32.16 Tetrapod Limbs Are Modified Fins The major skeletal elements of the tetrapod limb were already present in aquatic lobe—limbed fishes some 380 million years ago. The relative sizes and positions of these elements changed as lobe—limbed vertebrates moved to a terrestrial environment, where limbs were needed to support and move the animal's body on land.

An early split in the tetrapod tree (see [Figure 32.10](#)) led to two main groups of terrestrial

vertebrates: **amphibians**, most of which remained tied to moist environments, and the **amniotes**, many of which adapted to much drier conditions.

Amphibians usually require moist environments

Most modern amphibians are confined to moist environments because they lose water rapidly through the skin when exposed to dry air. In addition, their eggs are enclosed within delicate gelatinous envelopes that cannot prevent water loss in dry conditions. In some amphibian species, adults live mostly on land but return to fresh water to lay and fertilize their eggs ([Figure 32.17](#)). The fertilized eggs give rise to larvae that live in water until they undergo metamorphosis to become terrestrial adults. However, many amphibians (especially those in tropical and subtropical areas) have evolved a wide variety of additional reproductive modes and types of parental care. Internal fertilization, for example, evolved several times among amphibian species. Many species develop directly into adultlike forms from fertilized eggs laid on land or carried by the parents. Other species of amphibians are entirely aquatic, never leaving the water at any stage of their lives, and many of these species retain a larval—like morphology.

Figure 32.17 In and Out of the Water Many amphibian species have life cycles like the one diagrammed here, in which the early stages take place in water and the aquatic tadpole transforms into a terrestrial adult through metamorphosis. Some species of amphibians, however, have direct development (with no aquatic larval

stage), and others are aquatic throughout life.

Q: What is a potential advantage of maintaining an aquatic tadpole stage, even though the adults are terrestrial?

 Animation 32.2 **Life Cycle of a Frog** www.Life11e.com/a32.2

The more than 7,000 known species of amphibians living today belong to three major groups: the wormlike, limbless, tropical, burrowing, or aquatic caecilians ([Figure 32.18A](#)), the tailless frogs and toads (collectively called anurans) ([Figure 32.18B](#)), and the tailed salamanders ([Figure 32.18C and D](#)).

(A) *Gymnopsis multiplicata*

(C) *Gyrinophilus porphyriticus*

(D) *Eurycea waterlooensis*

Figure 32.18 Diversity among the Amphibians (A) Burrowing caecilians superficially look more like worms than like amphibians. They have internal fertilization and many species are viviparous. (B) Male golden toads in the cloud forest of Monteverde, Costa Rica. This is one of many amphibian species lost to extinction in the past few decades. (C) An adult spring salamander. This species has aquatic larvae but terrestrial adults. (D) This Austin blind salamander's life cycle is completely aquatic; it has no terrestrial stage. The eyes of this cave dweller are greatly reduced.

Anurans are most diverse in wet tropical and warm temperate regions, although a few are found at very high latitudes. There are far more anurans than any other amphibians, with well over 6,000 described species and more being discovered every year. Some anurans have tough skins and other adaptations that enable them to live for long periods in deserts, whereas others live in moist terrestrial and arboreal environments. Some species are completely aquatic as adults. All anurans have a short vertebral column and a pelvic region that is modified for leaping, hopping, or propelling the body through water by kicking the hind legs.

The more than 600 described species of salamanders are most diverse in temperate regions of the Northern Hemisphere and in cool, moist environments in the mountains of Central America, although a few species penetrate into tropical regions. Many salamanders live in rotting logs or moist soil. One major group has lost the lungs, and these species exchange gases entirely through the skin and mouth lining—body parts that all amphibians use, in addition to their lungs, for gas exchange. A completely aquatic lifestyle has evolved several times among the salamanders (see [Figure 32.18D](#)). These aquatic species have arisen through a developmental process known as **neoteny**, or the retention of juvenile traits (in this case, gills) by delayed somatic development. Most species of salamanders have internal fertilization, which

is usually achieved through the transfer of a small, jellylike, sperm—embedded capsule called a spermatophore.

neoteny (knee ot' enny) [Gk. *neo*: new, recent + *tenein*: to extend] The retention of juvenile or larval traits by the fully developed adult organism.

Many amphibians have complex social behaviors. Most male anurans utter loud, species—specific calls to attract females of their own species (and sometimes to defend breeding territories), and they compete for access to females that arrive at the breeding sites. Many amphibians lay large numbers of eggs, which they abandon once they are deposited and fertilized. Other amphibians lay only a few eggs, which are fertilized and then cared for. A few species of frogs, salamanders, and caecilians are viviparous, meaning that they give birth to well—developed young that have received nutrition from the female during gestation.

Media Clip 32.4 Answering a Mating Call www.Life11e.com/mc32.4

Amphibians are the focus of much attention today because populations of many species are declining rapidly, especially in mountainous regions of western North America, Central and South America, and northeastern Australia. Worldwide, about one—third of amphibian species are now threatened with extinction or have disappeared completely in the last few decades. Scientists are investigating several hypotheses to account for these ***amphibian declines**.

Amniotes colonized dry environments

Several key innovations for conserving water contributed to the ability of the amniotes to exploit a wide range of terrestrial habitats. The **amniote egg** (which gives the group its name) is relatively impermeable to water and allows the embryo to develop in a contained aqueous environment (**Focus: Key Figure 32.19A**). Its leathery or brittle, calcium—impregnated shell retards evaporation of the fluids inside but permits passage of oxygen and carbon dioxide. The amniote egg also stores large quantities of food in the form of **yolk**, allowing the embryo to attain a relatively advanced state of development before it hatches. Within the shell are **extraembryonic membranes** that protect the embryo from desiccation and assist it with gas exchange and excretion of nitrogenous waste products of metabolism.

focus: key figure

Figure 32.19 The Amniote Egg (A) The evolution of the amniote egg, with its water—retaining shell, four extraembryonic membranes, and embryo—nourishing yolk, was a major step in adaptation to the terrestrial environment. A chicken egg is shown

here. **(B)** In most mammals, the developing embryo is retained inside the mother's body, with which it exchanges nutrients and wastes via the placenta.

Activity 32.2 The Amniote Egg www.Life11e.com/ac32.2

Q: How were the various membranes in the amniote egg modified in mammals to support viviparity?

amniote egg A shelled egg surrounding four extraembryonic membranes and embryo-nourishing yolk. This evolutionary adaptation permitted mammals and reptiles to live and reproduce in drier environments than can most amphibians.

yolk [M.E. *yolke* : yellow] The stored food material in animal eggs, rich in protein and lipids.

extraembryonic membranes Four membranes that support but are not part of the developing embryos of reptiles, birds, and mammals, defining these groups phylogenetically as amniotes. (See amnion, allantois, chorion, yolk sac.)

▶ investigatinglife Have Shelled Eggs Re-Evolved among Viviparous Reptile Lineages?

experiment

Original Papers: Pyron, R. A. and F. T. Burbrink. 2014. Early origin of viviparity and multiple reversions to oviparity in squamate reptiles. *Ecological Letters* 17: 13–21.

Wright, A. M., K. M. Lyons, M. C. Brandley and D. M. Hillis. 2015. Which came first: The lizard or the egg? Robustness in phylogenetic reconstruction of ancestral states. *Journal of Experimental Zoology (Molecular and Developmental Evolution)* 324B: 504–516.

The shelled amniote egg is a complex structure, and the transition from oviparity to viviparity requires extensive changes in reproductive morphology and physiology. For example, oviparous species have uterine shell glands that secrete calcium for eggshell construction. These shell glands are modified in viviparous species to provide calcium to the developing embryo. Viviparity is thought to have evolved from oviparity more than 100 times among lizards and snakes, but biologists wondered if the process can be reversed: does egg laying ever re-evolve in live-bearing lineages?

Oviparous: Pueblan milk snake

Viviparous: Blotched blue-tongue lizard

QUESTION ▶ Can complex traits such as shelled eggs re-evolve once they have been lost?

METHOD

1. Reconstruct the phylogeny of lizards and snakes (squamates).
2. Collect data on the reproductive mode of more than 8,000 species of lizards and snakes.
3. Reconstruct the evolution of transitions between oviparity and viviparity on the phylogeny.

RESULTS

The number of reversals from viviparity to oviparity depends on the model of character change, but there is support for the re-evolution of egg laying from live birth in one group of lizards and in two groups of snakes.

CONCLUSION ▶ Although transitions from oviparity to viviparity are much more common than the reverse, egg laying may have re-evolved in a few lineages of squamates.

investigatinglife work with the data follows on next page

work with the data

Original Paper: Fenwick, A. M., H. W. Greene and C. L. Parkinson. 2012. The serpent and the egg: Unidirectional evolution of reproductive mode in vipers? *Journal of Zoological Systematics and Evolutionary Research* 50: 59–66.

The tree below shows a small portion of the phylogeny and reproductive data collected for squamates, from the New World pit vipers. Use this data sample to answer the questions.

QUESTIONS▶

1. Starting with a root state of oviparity, plot the minimum number of changes between oviparity and viviparity (in either direction) that is necessary to explain the distribution of reproductive states on the tree. What is the minimum number of changes required on this tree? Does that number include any reversals to oviparity?

2. Assume that the only changes that can occur are changes from oviparity to viviparity (do not allow any changes in the opposite direction). How many additional transitions in reproductive mode are necessary under this assumption compared with the result you obtained in Question 1?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

As we described in the opening of this chapter, modifications of the amniote egg in several different groups of amniotes allowed the embryo to develop inside (and exchange nutrients and wastes with) its mother's body (**Focus: Key Figure 32.19B**). For example, in most mammals the egg lost its shell entirely while the functions of the extraembryonic membranes were retained and expanded, giving rise to viviparity. Viviparity appears to have evolved many times among lizards and snakes. In **Investigating Life: Have Shelled Eggs Re-Evolved among Viviparous Reptile Lineages?**, we explore the possibility that shelled eggs could have re—evolved in some of these lineages.

Other innovations evolved in the organs of terrestrial adults. A tough, impermeable skin, covered with scales or modifications of scales such as hair and feathers, greatly reduced water loss. Adaptations of the kidneys (the vertebrate excretory organs), allowed amniotes to excrete concentrated urine, ridding the body of nitrogenous wastes without losing a large amount of water in the process (see [Chapter 51](#)).

During the Carboniferous, the amniotes split into two major groups: the **reptiles** and the lineage that eventually led to the **mammals** ([Figure 32.20](#)).

Figure 32.20 Phylogeny of Amniotes This tree of amniote relationships shows the primary split between mammals and reptiles. The reptile portion of the tree shows that one lineage led to the lepidosaurs (snakes, lizards, and tuataras), another to the turtles, and a third to the archosaurs (the crocodiles, several extinct groups, and the birds)

Reptiles adapted to life in many habitats

The lineage leading to modern reptiles began to diverge from other amniotes more than 300 million years ago. More than 19,000 species of reptiles exist today, more than half of which are birds. Birds are the only living representatives of the otherwise extinct dinosaurs, the dominant terrestrial vertebrates of the Mesozoic.

The **lepidosaurs** constitute the second most species—rich clad of living reptiles. This group is composed of the **squamates** (lizards, snakes, and amphisbaenians—the last a group of mostly legless, wormlike, burrowing reptiles with greatly reduced eyes) and the **tuataras**, which superficially resemble lizards but differ from them in possessing more rigid skulls and other anatomical features. Many species related to the tuataras lived during the Mesozoic era, but today only a single species survives ([Figure 32.21A](#)), and is restricted to a few islands off New Zealand.

(A) *Sphenodon punctatus*

(B) *Furcifer pardalis*

(C) *Orthriophis taeniura friesi*

(D) *Chelonoidis nigra abingdonii*

Figure 32.21 Reptilian Diversity (A) This tuatara represents the only surviving species in its lineage. **(B)** The panther chameleon is found in eastern and northern Madagascar. It uses its projectile tongue to capture insects. **(C)** The Taiwan beauty snake is a nonvenomous, semi-arboreal rodent eater. **(D)** Galápagos tortoises are the largest turtles and among the largest reptiles. They have been documented to live for more than 100 years in the wild.

The skin of a lepidosaur is covered with horny scales that greatly reduce loss of water from the body surface. These scales, however, make the skin unavailable as an organ of gas exchange. Gases are exchanged almost entirely via the lungs, which are proportionally much larger in surface area than those of amphibians. A lepidosaur forces air into and out of its lungs by bellows—like movements of its ribs. The three—chambered lepidosaur heart partially separates oxygenated blood from the lungs from deoxygenated blood returning from the body. With this type of heart, lepidosaurs can generate high blood pressure and can sustain a relatively high metabolism.

Most lizards are insectivores, although some are herbivores and a few prey on other vertebrates. Most lizards walk on four limbs ([Figure 32.21B](#)), although limblessness has evolved repeatedly among the lizards, especially in burrowing and grassland species. The largest lizard is the predaceous Komodo dragon of the East Indies, which grows as long as 3 meters and can weigh more than 150 kilograms.

Media Clip 32.5 Komodo Dragons Bring Down Prey www.Life11e.com/mc32.5

The major group of limbless squamates is the snakes ([Figure 32.21C](#)). All snakes are carnivores, and many can swallow objects much larger than themselves. Several snake groups possess venom glands and the ability to inject venom rapidly into their prey.

The **turtles** comprise a reptilian group that has changed relatively little since the early Mesozoic. In these reptiles, dorsal and ventral bony plates form a shell into which the head and limbs can be withdrawn in many species ([Figure 32.21D](#)). The dorsal shell is a modification of the ribs. It is notable that pectoral girdles are inside the ribs of turtles, making them unlike any other vertebrates. Most turtles live in aquatic environments, but several groups, such as tortoises and box turtles, are terrestrial. Sea turtles spend their entire lives at sea except when they come ashore to lay eggs. Human exploitation of sea turtles and their eggs has resulted in worldwide declines of these species, all of which are now endangered. A few species of turtles are strict herbivores or carnivores, but most species are omnivores that eat a variety of aquatic and terrestrial plants and animals.

Crocodylians and birds share their ancestry with the dinosaurs

Another reptilian clade, the **archosaurs**, includes the crocodylians, pterosaurs, dinosaurs, and birds. Only the crocodylians and birds are represented by living species today. Modern **crocodylians**—crocodiles, caimans, gharials, and alligators—are confined to tropical and warm temperate environments ([Figure 32.22A](#)). All crocodylians are carnivorous; they eat vertebrates of all kinds, including large mammals. Crocodylians spend much of their time in water, but they lay their eggs in nests they build on land or on floating piles of vegetation. The eggs are warmed by heat generated by decaying organic matter that the female places in the nest. The female provides other forms of parental care as well: typically she guards the eggs until they hatch, and in some species she continues to guard and communicate with her offspring after they hatch.

(A) *Crocodylus porosus*

(B) *Casuarius casuarius*

Figure 32.22 Archosaurs The two surviving groups of archosaurs are very different. **(A)** The crocodilians live in tropical and warm temperate climates. This saltwater crocodile lives in saltwater and estuarine environments along Australia's coast. **(B)** Birds are the only other living archosaur group, represented here by the winged but flightless southern cassowary.

Dinosaurs rose to prominence about 215 million years ago and dominated terrestrial environments for about 150 million years. However, only one group of dinosaurs, the **birds**, survived the mass extinction at the end of the Cretaceous. During the Mesozoic, most terrestrial animals more than a meter long were dinosaurs. Many were agile and could run rapidly; they had special muscles that enabled the lungs to be filled and emptied while the limbs moved. We can infer the existence of such muscles in dinosaurs from the structure of the vertebral column

in fossils. Some of the largest dinosaurs weighed as much as 70,000 kilograms.

Biologists have long accepted the phylogenetic position of birds among the reptiles, although birds clearly have many unique, derived morphological features. In addition to the strong morphological evidence for this placement, fossil and molecular data emerging over the last few decades have provided definitive supporting evidence. Birds are a specialized group of **theropods**, a clade of predatory dinosaurs that shared such traits as a bipedal stance, hollow bones, a furcula (“wishbone”), elongated metatarsals with three-fingered feet, elongated forelimbs with three fingers, and a pelvis that points backward. Modern birds are endothermic, meaning that they regulate their body temperatures by producing and retaining metabolic heat, rather than by absorbing heat from their external environment (see [Key Concept 39.4](#)). Although we cannot directly assess this physiological trait in extinct species, many fossil theropods share morphological traits that suggest they may have been endothermic as well.

The living bird species fall into two major groups that diverged about 80—90 million years ago from a flying ancestor. The few modern descendants of one lineage include a group of secondarily flightless and weakly flying birds, some of which are very large. This group, called the palaeognaths, includes the South and Central American tinamous and several large flightless birds of the southern continents—the rheas, emu, kiwis, cassowaries, and the world’s largest birds, the ostriches ([Figure 32.22B](#)). The second lineage, the neognaths, has left a much larger number of descendants, most of which have retained the ability to fly.

Feathers allowed birds to fly

Fossil theropods discovered in early Cretaceous deposits in Liaoning Province, in northeastern China, show that the scales of some small predatory dinosaurs were highly modified to form [feathers](#). Initially these feathers were simply a body covering that probably provided insulation and enhanced coloration. But the feathers of some later dinosaurs, such as *Microraptorgui*, were structurally similar to those of modern birds ([Figure 32.23A](#)).

(A)

Faint impressions of feathers can be seen around the fossilized skeletons.

(B)

Figure 32.23 Mesozoic Bird Relatives Fossils support the evolution of birds from other theropods. **(A)** *Microraptor gui* was a feathered theropod from the early Cretaceous (about 140 mya). **(B)** *Archaeopteryx* was even more closely related to modern birds.

feather A structure growing from the skin of theropods (living birds and their extinct relatives) that consists of a hollow shaft fringed with vanes of barbs. Functions to support flight, plumage display, and thermoregulation.

Another theropod that was even more closely related to modern birds, *Archaeopteryx*, lived about 150 million years ago. *Archaeopteryx* had teeth (unlike modern birds), but it was covered with feathers that are virtually identical to those of birds ([Figure 32.23B](#)). It also had well—developed wings, a long tail, and a furcula to which some of the flight muscles were probably attached. *Archaeopteryx* had clawed fingers on its forelimbs, but it also had typical perching bird claws on its hindlimbs. It probably lived in trees and shrubs and used the fingers to assist it in clambering over branches. It probably glided or flew weakly. The descendants of *Archaeopteryx* and similar Mesozoic theropods were the modern birds, most of which are accomplished fliers.

The evolution and specialization of feathers was a major force for diversification. Feathers are lightweight, but they are strong and structurally complex ([Figure 32.24](#)). The stiff central shaft of the flight feathers on a bird's wings arises from the skin of the forelimbs to create the flying surfaces. Other strong feathers sprout like a fan from the shortened tail and serve as stabilizers during flight. The feathers that cover the body, along with an underlying layer of down feathers, provide birds with insulation that helps them survive in virtually all of Earth's climates.

Figure 32.24 Feather Anatomy The flight feathers of birds are attached to the wing's skin by the hollow portion, or quill, of a stiff central shaft. The rachis is the solid portion of the shaft from which radiate fine branches (vanes) with interlocking hooks and barbules. Overall, this structure represents a major evolutionary innovation: a strong, lightweight surface that enables flight.

The bones of theropod dinosaurs, including birds, are hollow with internal struts that increase their strength. Hollow bones would have made early theropods lighter and more mobile; later they facilitated the evolution of flight. The sternum (breastbone) of flying birds forms a large, vertical keel to which the flight muscles are attached.

Flight is metabolically expensive. A flying bird consumes energy at a rate about 15–20 times faster than a running lizard of the same weight. Because birds have such high metabolic rates, they generate large amounts of heat. They control the rate of heat loss using their feathers, which may be held close to the body or elevated to alter the amount of insulation they provide. The lungs of birds allow air to flow through unidirectionally rather than pumping air in and out (see [Key Concept 48.2](#)). This flow—through structure of the lungs increases the efficiency of gas exchange and thereby supports a high metabolic rate.

There are about 10,000 species of living birds, which range in size from the 150-kilogram ostriches to a tiny hummingbird weighing only 2 grams ([Figure 32.25](#)). The teeth so prominent among other dinosaurs were secondarily lost in the ancestral birds, but birds nonetheless eat almost all types of animal and plant material. Insects and fruits are the most important dietary

items for terrestrial species. Birds also eat seeds, nectar and pollen, leaves and buds, carrion, and other vertebrates. By eating the fruits and seeds of plants, birds serve as major agents of seed dispersal.

(A) *Sialia mexicana*

(B) *Trichoglossus haematodus*

Mammals radiated after the extinction of non—avian dinosaurs

Small and medium—sized mammals coexisted with the large dinosaurs throughout most of the Mesozoic era, and most of the major groups of mammals that are alive today arose in the Cretaceous. After the non—avian dinosaurs disappeared during the mass extinction at the end of the Cretaceous, mammals increased dramatically in numbers, diversity, and size. Today mammals range in size from tiny shrews and bats weighing only about 2 grams to the blue whale, the largest animal on Earth, which measures up to 32 meters long and can weigh as much as 160,000 kilograms. Mammals have far fewer, but more highly differentiated, teeth than do fishes, amphibians, or reptiles. Differences among mammals in the number, type, and arrangement of teeth reflect their varied diets (see [Figure 50.6](#)).

Four key features distinguish the mammals:

- . *Sweat glands*, which secrete sweat that evaporates and there-by cools an animal
- . *Mammary glands*, which in females secrete a nutritive fluid (milk) on which newborn individuals feed
- . *Hair*, which provides a protective and insulating covering
- . A *four—chambered heart* that completely separates the oxygenated blood coming from the lungs from the deoxygen-ated blood returning from the body (this last characteristic is convergent with the archosaurs, including modern birds and crocodiles)

Mammalian eggs are fertilized within the female’s body, and in nearly all mammalian groups the resulting embryos undergo a period of development inside the female’s body in an organ called the uterus. In the uterus, the embryo is contained in an amniotic sac that is homologous to one of the four membranes found in the amniote egg (see Figure 32.19). The embryo is connected to the wall of the uterus by an organ called a placenta. The placenta allows for nutrient and gas exchange, as well as waste elimination from the developing embryo, via the female’s circulatory system. Most mammals develop a covering of hair (fur), which is luxuriant in some species but has been greatly reduced in others, including cetaceans (whales and dolphins) and humans. Thick layers of insulating fat (blubber) replace hair as a heat-retention mechanism in the cetaceans. Humans learned to use clothing for this purpose when they dispersed from warm tropical areas.

The approximately 5,700 species of living mammals are divided into two primary groups: the **prototherians** and the **therians** ([Table 32.1](#)). Members of the therian clade are further divided into the **marsupials** and the **eutherians**.

table 32.1 Major Groups of Living Mammals

Group	Number of described species	Examples
PROTOTHERIANS		
Monotremes (Monotremata)	5	Echidnas, duck—billed platypus
THERIANS		
Marsupials		
Diprotodonts (Diprotodontia)	146	Kangaroos, wallabies, possums, koala, wombats
New World opossums (Didelphimorphia)	93	Opossums
Carnivorous marsupials (Dasyuromorphia)	75	Quolls, dunnarts, numbat, Tasmanian devil
Omnivorous marsupials (Peramelemorphia)	24	Bandicoots and bilbies
Shrew opossums (Paucituberculata)	7	Andean rat opossums
Marsupial moles (Notoryctemorphia)	2	Southern and northern marsupial moles
Microbiothere (Microbiotherea)	1	Monito del monte
Eutherians		
Rodents (Rodentia)	2,337	Rats, mice, squirrels, woodchucks, ground squirrels, beaver, capybara
Bats (Chiroptera)	1,171	Fruit bats, echo—locating bats
Even—toed hoofed mammals and cetaceans (Cetartiodactyla)	469	Deer, sheep, goats, cattle, antelopes, giraffes, camels, swine, hippopotamus, whales, dolphins

Shrews, moles, and relatives (Soricomorpha)	428	Shrews, moles, solenodons
Primates (Primates)	396	Lemurs, monkeys, apes, humans
Carnivores (Carnivora)	284	Wolves, dogs, bears, cats, weasels, pinnipeds (seals, sea lions, walruses)
Rabbits and relatives (Lagomorpha)	92	Rabbits, hares, pikas
African insectivores (Afrosoricida)	50	Tenrecs, golden moles
Hedgehogs (Erinaceomorpha)	24	European hedgehog
Armadillos (Cingulata)	21	Giant armadillo, nine—banded armadillo
Tree shrews (Scandentia)	20	Pygmy tree shrew, pen—tailed tree shrew
Odd—toed hoofed mammals (Perissodactyla)	16	Horses, zebras, tapirs, rhinoceroses
Elephant shrews (Macroscelidea)	15	Elephant shrews, jumping shrews, sengis
Anteaters, sloths (Pilosa)	10	Anteaters, tamanduas, two— and three—toed sloths
Pangolins (Pholidota)	8	Asian and African pangolins
Hyraxes and relatives (Hyracoidea)	5	Hyraxes, dassies
Sirenians (Sirenia)	4	Manatees, dugongs
Elephants (Proboscidea)	3	African and Indian elephants
Colugos (Dermoptera)	2	Flying lemurs
Aardvark (Tubulidentata)	1	Aardvark

PROTOTHERIANS

Only five species of living prototherians are known, and they are found only in Australia and New Guinea. These mammals, the duck-billed platypus and four species of echidnas, differ from other mammals in laying shelled eggs and having sprawling legs ([Figure 32.26](#)). Prototherians supply milk for their young, but they have no nipples on their mammary glands; the milk simply oozes out and is lapped off the fur by the offspring.

(A) *Tachyglossus aculeatus*

(B) *Ornithorhynchus anatinus*

Figure 32.26 Prototherians (A) The short—beaked echidna is one of four surviving species of echidnas. **(B)** The duck—billed platypus lives in freshwater streams in eastern Australia.

MARSUPIALS Females of most marsupial species have a ventral pouch in which they carry and feed their offspring (see [Figure 32.27A](#)). Gestation (pregnancy) in marsupials is brief; the young are born tiny but with well—developed forelimbs, with which they climb to the pouch. They attach to a nipple but cannot suck. The mother ejects milk into the tiny offspring until it grows large enough to suckle. Once her offspring have left the uterus, a female marsupial may become sexually receptive again. She can then carry fertilized eggs that are capable of initiating development to replace the offspring in her pouch should something happen to them.

(A) *Macropus giganteus*

(B) *Myrmecobius fasciatus*

(C) *Didelphis virginiana*

Figure 32.27 Diversity among the Marsupials (A) Australia's eastern gray kangaroo is among the largest living marsupials. This female carries her young offspring in the characteristic marsupial pouch. (B) The diet of the banded anteater of western Australia consists almost entirely of termites. (C) The North American opossum is the only marsupial found north of Mexico.

At one time marsupials were found on all continents, but the approximately 350 living species are now restricted to Australasia ([Figure 32.27A and B](#)) and the Americas (especially South America) ([Figure 32.27C](#)). Of the seven major groups of marsupials shown in [Table 32.1](#), only the New World opossums, the shrew opossums, and the diminutive monito del monte are found in the Americas. Only one species, the Virginia opossum, is found in North America north of Mexico. Marsupials radiated to become herbivores, insectivores, and carnivores, but no marsupials live in the oceans. None can fly, although some arboreal (tree—dwelling) marsupials are gliders. The largest living marsupials are the kangaroos of Australia, which can weigh up to 90 kilograms. Much larger marsupials existed in Australia until humans exterminated them soon after reaching that continent about 40,000 years ago.

EUTHERIANS

The majority of mammals are eutherians (“true” therians). Eutherians are sometimes called placental mammals, but this name is inappropriate because marsupials also have placentas, although they are not as well developed as in eutherians. Eutherians are more developed at birth than are marsupials; no external pouch houses them after they are born.

The more than 5,300 species of living eutherians are divided into 20 major groups (see [Table 32.1](#)). The relationships of these groups to one another have been difficult to determine because most of the major groups diverged within a short time during an explosive adaptive radiation. Modern genomic analyses have elucidated these relationships, however ([Figure 32.28](#)). These studies have revealed that the major early splits in eutherian lineages are closely associated with the breakup of the continents during the Mesozoic (see [Figure 24.14](#)), after which the major groups of mammals radiated independently in Laurasia, Africa, and South America. The reconnection of South America and North America via the Panamanian land bridge about 3 million years ago resulted in a huge faunal exchange between those continents, which is particularly evident among the mammals. South American groups such as armadillos moved north into North America, and Laurasian groups such as carnivores and odd- and even-toed hoofed animals moved south into South America.

Figure 32.28 Major Groups of Eutherians Diversified as the Continents Drifted Apart This phylogenetic tree shows the relationships among most of the major terrestrial eutherian groups, the location of the earliest fossils found for each group (also indicated in the color distinctions of the various branches), and the current distributions of the groups. The major splits in eutherian evolution correspond in large degree to the tectonic history of the major continents (see [Figures 24.14](#) and [53.14](#)).

Eutherians are extremely varied in their form and ecology ([Figure 32.29](#)). The extinction of the non—avian dinosaurs at the end of the Cretaceous may have made it possible for them to diversify and radiate into a large range of ecological niches. Many eutherian species grew large, and some assumed the roles of dominant terrestrial predators previously occupied by the large dinosaurs. Among these predators, social hunting behavior evolved in several species, including members of the carnivore and primate clades.

(A) *Castor canadensis*

(B) *Plecotus townsendii*

(C)

(D) *Tursiops truncatus*

Figure 32.29 Diversity among the Eutherians (A) The North American beaver exhibits the gnawing teeth that characterize rodents. Almost half of all eutherians are rodents. (B) Flight evolved in the ancestor of bats. This Townsend's big-eared bat uses its enlarged ears to detect insect prey by echolocation. (C) Large hoofed mammals such as giraffes, zebras, and springboks are major herbivores of grasslands

and savannahs. **(D)** Bottle nosed dolphins are cetaceans, a cetartiodactyl group that returned to the marine environment.

The two most diverse groups of eutherians are the rodents and the bats, which together account for about two—thirds of the species. Rodents are traditionally defined by the unique morphology of their teeth, which are adapted for gnawing through substances such as wood. The bats probably owe much of their success to the evolution of flight, which allows them to exploit a variety of food sources and colonize remote locations with relative ease.

 Media Clip 32.7 **Bats Feeding in Flight** www.Life11e.com/mc32.7

Grazing and browsing by members of several eutherian groups helped transform the terrestrial landscape. Herds of grazing herbivores fed on open grasslands, whereas browsers fed on shrubs and trees. The effects of these herbivores on plant life favored the evolution of the spines, tough leaves, and difficult—to—eat growth forms found in many plants. In turn, adaptations in the teeth and digestive systems of many herbivore lineages allowed these species to consume many plants despite such defenses—a striking example of coevolution. A large animal can survive on food of lower quality than a small animal can, and large size evolved in several groups of grazing and browsing mammals (see [Figure 32.29C](#)). The evolution of large herbivores, in turn, favored the evolution of large carnivores able to attack and overpower them.

Several lineages of terrestrial eutherians subsequently returned to the aquatic environments their ancestors had left behind (see [Figure 32.29D](#)). The completely aquatic cetaceans—whales and dolphins—evolved from even—toed hoofed ancestors (whales are closely related to the hippopotamuses). The seals, sea lions, and walruses also returned to the marine environment, and their limbs became modified into flippers. Weasel—like otters retain their limbs but have also returned to aquatic environments, colonizing both fresh and salt water. The manatees and dugongs colonized estuaries and shallow seas.

32.4 recap

The initial vertebrate colonization of dry land was facilitated by the evolution of lunglike sacs and jointed limbs. The amniotes also evolved impermeable body coverings, efficient kidneys, and the amniote egg, which resists desiccation.

learning outcomes

You should be able to:

- Explain how features of amphibians can make them especially vulnerable to environmental change.
- Summarize the evidence showing that birds are indeed reptiles.
- Describe how a mass extinction affected the diversification of mammals.
- Trace the evolution of endothermy, hair, and feathers across the phylogeny of amniotes.
- Describe how major changes in Earth's geology and climate have affected the evolution of tetrapods.

1. Amphibians have survived and prospered for millions of years, but today many species are disappearing and populations of others are in serious decline. What features of their life histories might make amphibians especially vulnerable to the kinds of environmental

changes now happening on Earth?

2. How has the diversification of mammals been influenced by mass extinction events and continental drift?
3. In the not-too-distant past, the idea that birds were reptiles met with skepticism. Explain how fossils, morphology, and molecular evidence now support the position of birds among the reptiles.
4. Consider the phylogeny of the amniotes and the evolution of endothermy, hair, and feathers. Which of these traits likely evolved convergently in more than one lineage? What is a likely functional relationship among these traits? Why do many paleontologists think that several extinct theropods were endothermic?

The biology of one eutherian group—the primates—has been the subject of extensive research. The behavior, ecology, physiology, and molecular biology of the primates are of special interest to us because this lineage includes humans.

***connect the concepts** One of the major factors associated with amphibian declines is the global spread of a pathogenic chytrid fungus, as explored in [Key Concept 29.2](#) and [Figure 29.6](#).

32.5 Humans Evolved among the Primates

One lineage of small, arboreal, insectivorous eutherians underwent extensive evolutionary radiation to become the **primates** ([Figure 32.30](#)).

Grasping limbs with opposable digits, an adaptation to arboreal life, are one of the major features that distinguish primates from other mammals.

Figure 32.30 Phylogeny of the Primates The phylogeny of primates is among the best studied of any major group of mammals. This tree is based on evidence from

many genes, morphology, and fossils.

focus your learning

The two major groups of primates are the wet—nosed primates (lemurs, lorises, and galagos) and the dry—nosed primates (tarsiers, Old and New World monkeys, and apes).

Possibly driven by an increasingly complex social life, larger brains evolved in one lineage of the genus *Homo*.

Two major lineages of primates split late in the Cretaceous

About 90 million years ago, late in the Cretaceous period, the primates split into two clades: the wet—nosed primates (strepsirrhines) and the dry—nosed primates (haplorhines). **Wet-nosed primates**—lemurs, lorises, and galagos—once lived on all continents, but today they are restricted to Africa, Madagascar, and tropical Asia. All mainland wet—nosed primate species are arboreal and nocturnal. On the island of Madagascar, however, the site of a remarkable radiation of lemurs, there are also diurnal and terrestrial species ([Figure 32.31](#)). Tarsiers were once considered a part of this lineage as well, although today we know that they are more closely related to **simians**—monkeys and apes—than to lemurs, lorises, and galagos.

Varecia variegata variegata

Figure 32.31 A Wet-Nosed Primate The diademed sifaka is one of the many lemur species found in Madagascar, where it is part of a unique assemblage of endemic plants and animals. Sifakas live in groups of up to a dozen animals and defend their territories.

The second primate lineage, the **dry—nosed primates**—tarsiers, New World monkeys, Old World monkeys, and apes—began to diversify shortly after the mass extinction event at the end of the Cretaceous, in Africa or Asia. New World monkeys diverged from Old World monkeys and apes slightly later, but early enough that they may have originated in Africa and reached South America when those two continents were still close to each other. New World monkeys now live only in South and Central America, and all of them are arboreal ([Figure 32.32A](#)). Many of them have a long, prehensile tail with which they can grasp branches. Many Old World monkeys are arboreal as well, but several species are terrestrial ([Figure 32.32B](#)). No Old World monkey has a prehensile tail.

(A) *Ateles geoffroyi*

(B) *Mandrillus sphinx*

Figure 32.32 Monkeys (A) The spider monkeys of Central America are typical of the New World monkeys, all of which are arboreal. Note the prehensile (gripping) tail. (B) Although many Old World monkeys are arboreal, none has a prehensile tail. Many Old World monkey species, like this mandrill, are thoroughly terrestrial.

About 35 million years ago, a lineage that led to the modern apes separated from the Old World monkeys. Between 22 and 5.5 million years ago, dozens of species of apes lived in Europe, Asia, and Africa. The Asian apes—gibbons and orangutans ([Figure 32.33A and B](#))—descended from two of these ape lineages. Orangutans are the closest living sister group of the

modern African apes: gorillas ([Figure 32.33C](#)), chimpanzees ([Figure 32.33D](#)), and humans.

(A) *Hylobates lar*

(B) *Pongo pygmaeus*

(C) *Gorilla gorilla*

(D) *Pan troglodytes*

Figure 32.33 Apes (A) The several genera of gibbons are all smaller in size than the other apes. Gibbons are found throughout Southeast Asia. (B) Orangutans are also native to Asia, living in the forests of Sumatra and Borneo. (C) Gorillas—the largest apes—are restricted to humid African forests. This male is a lowland gorilla. (D) Chimpanzees, our closest relatives, are found in forested regions of Africa.

Bipedal locomotion evolved in human ancestors

About 6 million years ago in Africa, a lineage split occurred that would lead to the chimpanzees on the one hand and to the **hominin** clade, which includes modern humans and their extinct close relatives, on the other.

hominin Lineages that includes modern humans (*Homo sapiens*) and their extinct ancestors (e.g., Australopithecines, *Homo erectus*).

The earliest protohominins, known as ardipithecines, had distinct morphological adaptations for **bipedal locomotion** (walking on two legs). Bipedal locomotion frees the forelimbs to manipulate objects and to carry them while walking. It also elevates the eyes, enabling the animal to see over tall vegetation to spot predators and prey. Bipedal locomotion is also energetically more economical than quadrupedal locomotion (walking on four legs). All three advantages were probably important for the ardipithecines and their descendants, the australopithecines (**Figure 32.34**).

Figure 32.34 A Phylogenetic Tree of Hominins At times in the past, more than one hominin species lived on Earth at the same time. Originating in Africa, hominins spread to Europe and Asia multiple times. All but one of those species are now extinct, but that one species, modern *Homo sapiens*, has colonized nearly every corner of the planet.

bipedal locomotion Terrestrial locomotion by means of two rear limbs or legs.

The first australopithecine skull was found in South Africa in 1924. Since then australopithecine fossils have been found at many sites in Africa. The most complete fossil skeleton yet found was discovered in Ethiopia in 1974. The skeleton, approximately 3.5 million years old, was that of a young female who has since become known to the world as “Lucy.” Lucy was assigned to the species *Australopithecus afarensis*. Fossil remains of more than 100 *A. afarensis* individuals have since been discovered, and there have been recent discoveries of fossils of other australopithecine species that lived in Africa 4–5 million years ago.

Experts disagree over how many species are represented by australopithecine fossils, but it is clear that multiple species of hominins lived together over much of eastern Africa several million years ago. A lineage of larger species (weighing about 40 kilograms) is represented by *Paranthropus robustus* and *P. boisei*, both of which died out between 1 and 1.5 million years ago. A lineage of smaller australopithecines gave rise to the genus *Homo*.

Early members of the genus *Homo* lived contemporaneously with *Paranthropus* in Africa for about a million years. Some 2-million-year-old fossils of an extinct species called *H. habilis* were discovered in the Olduvai Gorge, Tanzania. Other fossils of *H. habilis* have been found in Kenya and Ethiopia. Associated with these fossils were tools that these early hominins used to obtain food.

Another extinct hominin species, *Homo erectus*, arose in Africa about 1.6 million years ago. Soon thereafter it had spread as far as eastern Asia, becoming the first hominin to leave Africa. Members of *H. erectus* were nearly as large as modern people, but their brains were smaller

and they had comparatively thick skulls. The cranium, which had thick, bony walls, may have been an adaptation to protect the brain, ears, and eyes from impacts caused by a fall or a blow from a blunt object. What would have been the source of such blows? Fighting with other *H. erectus* individuals is a possible answer.

Homo erectus used fire for cooking and for hunting large animals, and made characteristic stone tools that have been found in many parts of Africa and Asia. Populations of *H. erectus* survived until at least 250,000 years ago, although more recent fossils may also be attributable to this species. In 2004 some 18,000-year-old fossil remains of a small *Homo* were found on the island of Flores in Indonesia. Since then, numerous additional fossils of this diminutive hominin have been found on Flores, dating from about 500,000 to 12,000 years ago, when a major volcanic eruption on Flores likely led to their extinction. Many anthropologists think that this small species, named *H. floresiensis*, was most closely related to *H. erectus*.

Human brains became larger as jaws became smaller

In another hominin lineage that diverged from *H. erectus* and *H. floresiensis*, the brain increased rapidly in size, and the jaw muscles, which were large and powerful in earlier hominins, dramatically decreased in size. These two changes were simultaneous, which suggests that they might have been developmentally linked. These changes are another example of evolution by neoteny (which, you may recall from our discussion of amphibians, is the retention of juvenile traits through delayed somatic development). Human and chimpanzee skulls are similar in shape at birth, but chimpanzee skulls undergo a dramatic change in shape as the animals mature ([Figure 32.35](#)). In particular, the jaw grows considerably in relation to the brain case. As human skulls grow, relative proportions much closer to those of the juvenile skull are retained, which results in a large brain case and small jaw compared with those of chimpanzees. A mutation in a regulatory gene that is expressed only in the head may have removed a barrier that had previously prevented this remodeling of the human cranium.

Figure 32.35 Neoteny in the Evolution of Humans The skulls and heads of juvenile

chimpanzees and humans start out relatively similar in shape. The grid over the skulls shows how the various bony elements change in their relative proportions over the course of maturation. The adult human skull retains a shape closer to its juvenile shape, resulting in a brain that is much larger relative to other parts of the skull (notably the jaw).

The striking enlargement of the brain relative to body size in the hominin lineage was probably favored by an increasingly complex social life. Any features that allowed group members to communicate more effectively with one another would have been valuable in cooperative hunting and gathering as well as for improving one's status in the complex social interactions that must have characterized early human societies, just as they do ours today.

Several *Homo* species coexisted during the mid—Pleistocene, from about 1.5 million to about 250,000 years ago. All were skilled hunters of large mammals, but plants were important components of their diets as well. During this period another distinctly human trait emerged: rituals and a concept of life after death. Deceased individuals were buried with tools and clothing, supplies for their presumed existence in the next world.

One species, *Homo neanderthalensis*, was widespread in Europe and Asia between about 500,000 and 28,000 years ago. Neanderthals were short, stocky, and powerfully built. Their massive skull housed a brain somewhat larger than our own. They manufactured a variety of tools and hunted large mammals, which they probably ambushed and subdued in close combat. A closely related lineage, the Denisovans, is known from less complete fossils, primarily from from Asian caves.

Recently, biologists have been able to extract DNA from the bones of Neanderthals and Denisovans, and have compared the genomes of these species to those of modern humans. Early modern humans (*H. sapiens*) expanded out of Africa between 70,000 and 60,000 years ago. Then, about 35,000 years ago, *H. sapiens* moved into the range of *H. neanderthalensis* in Europe and western Asia, and into the range of the Denisovans in eastern Asia. Neanderthals abruptly disappeared about 28,000 years ago. Many anthropologists believe that Neanderthals and Denisovans were exterminated by those early modern humans. But comparisons of Neanderthal, Denisovan, and modern human genomes indicate that there was some limited interbreeding among these species while they occupied the same range. In humans with Eurasian ancestry, 1—4 percent of the genes in their genomes may be derived from Neanderthal ancestors. The genomes of some modern native people of Southeast Asia, Melanesia, and Australia contain even higher proportions of Denisovan genes. So all three of these lineages contributed in some degree to modern humans.

Early modern humans made and used a variety of sophisticated tools. They created the remarkable paintings of large mammals, many of them showing scenes of hunting, found in European caves. The animals they depicted were characteristic of the cold steppes and grasslands that occupied much of Europe during periods of glacial expansion. Early modern humans also spread across Asia, reaching North America perhaps as early as 20,000 years ago, although the date of their arrival in the Americas is still uncertain. Within a few thousand years, they had spread southward through North America to the southern tip of South America.

Humans developed complex language and culture

As our ancestors evolved larger brains, their behavioral capabilities increased, especially the capacity for language. Most animal communication consists of a limited number of signals, which refer mostly to immediate circumstances and are each used in a specific context. Human language is far richer in its symbolic character than other animal vocalizations. Our words can refer to past and future times and to distant places. We are capable of learning thousands of words, many of them referring to abstract concepts. We can rearrange words to form sentences with complex meanings.

The expanded mental abilities of humans enabled the development of a complex culture, in

which knowledge and traditions are passed along from one generation to the next by teaching and observation. Cultures can change rapidly because genetic changes are not necessary for a cultural trait to spread through a population. Cultural norms, however, are not transferred automatically and must be deliberately taught to each generation.

Cultural transmission greatly facilitated the domestication of plants and animals and the resultant conversion of most human societies from ones in which food was obtained by hunting and gathering to ones in which pastoralism (herding large animals) and agriculture provided most of the food. The development of agriculture led to an increasingly sedentary life, the growth of cities, greatly expanded food supplies, rapid increases in the human population, and the appearance of occupational specializations, such as artisans, shamans, and teachers.

32.5 recap

Grasping limbs with opposable digits distinguish primates from other mammals. Bipedal locomotion and large brains evolved in the primate ancestors that led to humans, which facilitated the development of complex language and culture.

learning outcomes

You should be able to:

- Summarize the diversity within the primates.
 - Articulate the relationship between bigger brains, smaller jaws, and neoteny.
-
1. Describe the differences between Old World and New World monkeys.
 2. Explain how neoteny resulted in the development of humans with relatively large brains and small jaws.

investigatinglife

QA What are the advantages and disadvantages of egg laying versus live birth?

Oviparity and viviparity involve some trade-offs of parental resources. In egg-laying species, all the nutrition for the developing embryo is supplied in the yolk. This means there is no continuing drain of parental resources as the embryo develops. One advantage of oviparity is that a female can often produce more offspring (since she devotes fewer resources to each one). Clutch size is often larger in oviparous species of lizards and snakes than in closely related viviparous species, although there are exceptions. Because each offspring in oviparous species receives a smaller parental investment compared with offspring of viviparous species, hatchlings tend to be smaller than the offspring of viviparous species.

Why is it sometimes advantageous for a species to commit more resources to fewer offspring? Developing embryos are retained in females in viviparous species, so females can control the temperature of development by behavioral thermoregulation. In high elevation and other cool environments, for example, females can bask in the sun during the day, and then retreat to cover at night. In addition, sometimes survival of offspring may depend on larger size and more parental investment. For example, in areas with short growing seasons and relatively cold temperatures, producing a few large offspring may yield significantly more descendants than producing a large number of small offspring that are less likely to survive. In contrast, in a favorable environment with abundant resources, producing many smaller offspring is likely to produce the most descendants.

Indeed, there is a correlation between reproductive mode and elevational range in many groups of squamates, with oviparous species occurring at lower elevations and viviparous species at higher elevations.

Future directions

It is comparatively easy, from evolutionary and physiological points of view, for viviparity to evolve from oviparity in squamates. The membranes of the amniote egg can be modified to provide maternal nutrition, as well as gas and waste exchange (see [Figure 32.19](#)). Evolutionary reversal—from viviparity to oviparity—is more difficult, since complex modifications for shell deposition, independent growth, and hatching from the shell need to re-evolve. Nonetheless, a few candidate squamate lineages (including the huge venomous bushmasters of Central and South America) have been identified in which such reversals appear to have occurred. Biologists are focusing on these exceptional reversals to learn how lineages may redevelop structures and physiological processes that were lost in ancestors that lived millions of years earlier.

► 32.1 Deuterostomes Include Echinoderms, Hemichordates, and Chordates

- Deuterostomes vary greatly in adult form, but based on the distinctive patterns of early development they share and on phylo-genetic analyses of their gene sequences, they are judged to be monophyletic.
- There are far fewer species of deuterostomes than of protostomes, but many deuterostomes are large and ecologically important.
- The deuterostomes comprise three major clades: the **echinoderms**, **hemichordates**, and **chordates**. **Review** [Figure 32.1](#), [Activity 32.1](#), [Animation 32.1](#)

► 32.2 Echinoderms and Hemichordates Are Restricted to Marine Environments

- Echinoderms and hemichordates, together called **ambulacrarians**, have bilaterally symmetrical, ciliated larvae. Adult echinoderms have [pentaradial symmetry](#) and an **oral**—**aboral** body orientation. **Review** [Figure 32.3](#)

pentaradial symmetry Symmetry in five or multiples of five; a feature of adult echinoderms.

- The **xenoturbellids** and **acoels** are reduced, soft—bodied wormlike marine animals with few distinct organ systems. Their relationships are uncertain, but recent analyses suggest that they may be the sister group of the ambulacrarians.
- Echinoderms have an [internal skeleton](#) of calcified plates and a unique [water vascular system](#) connected to extensions called [tube feet](#). **Review** [Figure 32.3](#)

internal skeleton See endoskeleton.

water vascular system In echinoderms, a network of water-filled canals that functions in gas exchange, locomotion, and feeding.

tube feet A unique feature of echinoderms; extensions of the water vascular system, which functions in gas exchange, locomotion, and feeding.

- Hemichordates are bilaterally symmetrical and have a three—part body divided into a proboscis, collar, and trunk. **Review** [Figure 32.6](#)

► 32.3 Chordates Have a Dorsal Nerve Cord and a Notochord

- Chordates fall into three principal clades: **lancelets**, **tunicates**, and **vertebrates**.
- At some stage in their development, all chordates have a dorsal hollow nerve cord, a post—anal tail, and a [notochord](#). Lancelets have all three key chordate features as adults. Tunicates have these features as larvae but most species lose them as adults. **Review** [Figure 32.7](#)

notochord (no' tow kord) [Gk. *notos*: back + *chorde*: string] A flexible rod of gelatinous material serving as a support in the embryos of all chordates and in the adults of tunicates and lancelets.

- The vertebrate body is characterized by an internal skeleton, which is supported by a **vertebral column** that usually replaces the notochord. It is also characterized by internal organs suspended in a coelom, a ventral heart, and an anterior skull enclosing a large brain. **Review Figure 32.9**

vertebral column [L. *vertere*: to turn] The jointed, dorsal column that is the primary support structure of vertebrates.

- From estuarine ancestors, vertebrates diversified into many lineages of marine and freshwater fishes. One of these lineages, the lobe—limbed vertebrates, later radiated into terrestrial environments. **Review Figure 32.10**
- In the **gnathostomes**, jaws evolved from gill arches. Jaws enabled these vertebrates to grasp large prey and, together with teeth, allowed them to cut food into small pieces. **Review Figure 32.12**
- **Chondrichthyans** have skeletons of cartilage; almost all species are marine. The skeletons of **ray—finned fishes** are made of bone; these fishes have colonized all aquatic environments.

▶ 32.4 Life on Land Contributed to Vertebrate Diversification

- Lungs and jointed appendages enabled one lineage of **lobelimbbed vertebrates** to colonize the land. This lineage gave rise to the **tetrapods**. **Review Figure 32.16**
- The earliest split in the tetrapod tree is between the **amphibians** and the **amniotes (reptiles and mammals)**.
- Most modern amphibians are confined to moist environments because their bodies and their eggs lose water rapidly. **Review Figure 32.17, Animation 32.2**
- An impermeable skin, efficient kidneys, and an **amniote egg** that could resist desiccation evolved in the amniotes. **Review Focus: Key Figure 32.19, Activity 32.2, Investigating Life: Have Shelled Eggs Re—Evolved among Viviparous Reptile Lineages?**

amniote egg A shelled egg surrounding four extraembryonic membranes and embryo-nourishing yolk. This evolutionary adaptation permitted mammals and reptiles to live and reproduce in drier environments than can most amphibians.

- The major living reptile groups are the **lepidosaurs (tuataras, along with the squamates, which include lizards, snakes, and amphisbaenians)**, the **turtles**, and the **archosaurs (crocodilians and birds)**. **Review Figure 32.20**
- Birds evolved from a group of active, predatory dinosaurs known as **theropods**. Feathers arose among the theropods, originally for insulation and to enhance coloration, but eventually developed into adaptations for flight in birds. **Review Figures 32.23, 32.24**
- Mammals are unique among animals in supplying their young with a nutritive fluid (milk) secreted by mammary glands. There are two primary mammalian clades: the **prototherians** (of which there are only five species) and the species—rich **therians**. The therian clade is further subdivided into the **marsupials** and the **eutherians**. **Review Table 32.1**
- Mammalian phylogeny is strongly associated with the breakup of the major continents during the Mesozoic. Major lineages of eutherians diversified in Laurasia, Africa, and

South America. **Review** [Figure 32.28](#)

► 32.5 Humans Evolved among the Primates

- Grasping limbs with opposable digits distinguish **primates** from other mammals. The **wet—nosed primate** clade includes the lemurs, lorises, and galagos; the **dry—nosed primate** clade includes tarsiers, monkeys, and apes. **Review** [Figure 32.30](#)
- The ancestors of **hominins** were terrestrial apes that developed efficient **bipedal locomotion**. **Review** [Figure 32.34](#)

hominin Lineages that includes modern humans (*Homo sapiens*) and their extinct ancestors (e.g., Australopithecines, *Homo erectus*).

bipedal locomotion Terrestrial locomotion by means of two rear limbs or legs.

- In the lineage leading to *Homo*, brains became larger as jaws became smaller; the two events appear to be developmentally linked and are an example of evolution via **neoteny**. **Review** [Figure 32-35](#)

Review

2.4 Modifications of the amniote egg allowed the embryo to develop inside its mother's body.

Lambert, S. M. and J. J. Wiens. 2013. Evolution of viviparity: A phylo—genetic test of the cold—climate hypothesis in phrynosomatid lizards. *Evolution* 67: 2614—2630.

Viviparity is estimated to have originated more than 100 times in squamate reptiles, making this an excellent group for the study of environmental conditions that favor live birth in ectothermic vertebrates. Fence lizards (*Sceloporus*) are a large, diverse clade that exhibits both oviparous and viviparous modes of reproduction. The “cold-climate” hypothesis suggests that viviparity is more likely to evolve in cooler environments. If this hypothesis is correct, then lizards in cooler environments (such as at higher elevations) should be more likely to evolve viviparity.

Researchers at the University of Arizona tested this hypothesis using a combination of temperature records and phylogenetic comparative methods.

They constructed a phylogenetic tree that included (1) a time—calibrated phylogeny of *Sceloporus* species, (2) reproductive mode of *Sceloporus* species on the tips of the tree (solid = oviparous, open = viviparous), (3) node labels reflecting reproductive mode according to the likelihood of reconstructed ancestral states, and (4) color—coded lineages reflecting mean temperature at the warmest quarter of the year, since this is when lizards typically produce eggs or offspring.

Questions

1. What does the phylogenetic tree suggest about the evolution of viviparity as it relates to environmental conditions? According to the cold—climate hypothesis, why would viviparity provide an advantage in cold environments?
2. Describe at least one advantage and one disadvantage of both viviparous and oviparous modes of reproduction
3. Viviparity evolved only once in extant lineages of mammals, more than 100 million years ago. Using the phylogeny provided on [page 714](#), describe at least two logistical reasons why squamates offer a more suitable group to study the selective forces leading to viviparity.
4. The maternal manipulation hypothesis for the evolution of viviparity in squamate reptiles claims that gravid females can select optimal body temperatures for developing eggs through sun—seeking or sun—avoidance behaviors, and these temperatures are different from those available in external nests. Assume you are a research scientist with infinite resources. Design an experiment to test this hypothesis.

PART EIGHT Flowering Plants: Form and Function

33

The Plant Body

Plants such as this old tree have roots, stems and leaves that perform the functions of the organism.

key concepts

- [3.1 The Plant Body Is Organized in a Distinctive Way](#)
- [3.2 Plant Organs Are Made Up of Three Tissue Systems](#)
- [3.3 Meristems Build a Continuously Growing Plant.](#)
- [3.4 Domestication Has Altered Plant Form](#)

Bread of the Tropics

To North Americans and Europeans, it is tapioca. To Central and South Americans, it is yuca. To Africans, it is manioc or bananku. The roots of the cassava plant, *Manihot esculenta*, are important in the diets of more than 800 million people. Cassava is grown mostly by family farmers for their own consumption. The root of the plant is a store of starch, which can be hydrolyzed and used by the plant as the stems and leaves grow. Other crop plants such as rice and wheat apportion about 35 percent of the total carbon fixed in photosynthesis into their storage organs (the grains), whereas cassava apportions an astounding 80 percent into the root, as starch. For humans, this is a convenient and concentrated source of food energy. Indeed, cassava has been nicknamed the "bread of the tropics" because, just as wheat bread is the major starchy food in the Western world, cassava supplies the starch in tropical areas.

Most cassava plants are clones. The plants have wide adaptability and grow well in dry soils, in both hot and cool climates. Typically, the farmer breaks off some pieces of stem and plants them. Because most plant cells are totipotent (see [Key Concept 19.1](#)) some of the stem cells dedifferentiate and form roots, while others become growing shoots. A whole new plant develops, and the roots are ready to eat 6 months to 2 years later.

There are countless recipes for preparing cassava as food, but it is nutritionally incomplete. Although rich in carbohydrates, cassava is a relatively poor source of protein, a requirement for the human diet. Eating cassava presents other difficulties. Cassava roots and leaves contain cyanogenic compounds, which are converted to cyanide by enzymes released when the cells are broken open. Cyanide is highly toxic and potentially lethal because it blocks electron transport in the mitochondria. Therefore it is essential to soak, cook, or ferment cassava, to break down the cyanogenic compounds and eliminate the cyanide, before it can be eaten safely. In all probability, the plant uses cyanide production as a protection against predators that eat it.

We open with the topic of cassava because it offers a preview of a wide range of studies embraced by the discipline of plant physiology. Plant physiology is a broad subject, covering photosynthesis, transport, plant nutrition, regulation of growth and development, reproduction, and the interactions between plants and their environments.

How might plant biologists improve the cassava plant for human use?

33.1 The Plant Body Is Organized in a Distinctive Way

Plants harvest energy from sunlight and collect water and mineral nutrients from the atmosphere and the soil. Because these resources are sometimes limited, plants must collect them from large areas, both above and below the ground. The plant is further challenged by its inability to move; a plant cannot, for example, relocate from a dry, shady location to one that is wet and sunny. The plant body plan responds to these challenges in two ways:

- Stems, leaves, and roots enable a plant anchored to one spot to capture scarce resources effectively, both above and below the ground.
- Plants can grow throughout their lifetimes, enabling them to respond to environmental cues. A plant can redirect its growth to exploit opportunities in its immediate environment; for example, it can extend its roots toward a water supply.

focus your learning

Plant growth patterns reflect challenges imposed by scarce resources and an inability to move.

Plant development is influenced by apical meristems, totipotency, vacuoles, and cell walls.

Two basic patterns that develop early in plant embryogenesis are apical-basal polarity and radial symmetry.

[Chapters 27](#) and [28](#) described how modern plants came from aquatic ancestors, giving rise to simple land plants and then to vascular plants. Despite their obvious differences in size and form, all vascular plants have essentially the same simple structural organization. This chapter describes the basic architecture of the largest group of vascular plants, the angiosperms (flowering plants), and shows how so much diversity can literally grow out of such a simple, basic form. There are more than 250,000 angiosperm species. A major distinguishing feature of angiosperms is flowers, which consist of modified leaves and stems and carry the organs for sexual reproduction. We will examine the structures and functions of flowers in detail in [Chapter 37](#).

In this chapter we'll focus on the three kinds of **vegetative** (nonsexual) organs that angiosperms possess: roots, stems, and leaves. Each of these vegetative organs can be understood in terms of its structure. By structure we mean both the overall form of the organ (its morphology) and the arrangement of its cells and tissues (its anatomy).

vegetative Nonreproductive, nonflowering, or asexual.
--

Plant organs are organized into two systems ([Figure 33.1](#)):

Figure 33.1 Vegetative Organs and Systems The basic plant body plan, with root and shoot systems, and the principal vegetative organs.

- The **root system** anchors the plant in place, absorbs water and dissolved minerals, and stores the products of photosynthesis from the shoot system. The extreme branching of plant roots and their high surface area-to-volume ratios allow them to absorb water and mineral nutrients from the soil efficiently.

root system The organ system that anchors a plant in place, absorbs water and dissolved minerals, and may store products of photosynthesis from the shoot system.

- The **shoot system** of a plant consists of the stems, leaves, and flowers. Broadly speaking, the **leaves** are the chief organs of photosynthesis. The **stems** hold and display the leaves to the sun and provide connections for the transport of materials between roots and leaves.

shoot system In plants, the organ system consisting of the leaves, stem(s), and flowers.

stem In plants, the organ that holds leaves and/or flowers and transports and distributes materials among the other organs of the plant.

Shoots and roots are composed of repeating modules called **phytomers**. Each phytomer in the shoot consists of a **node** carrying one or more leaves; an **internode**, which is the interval of stem between two nodes; and one or more **axillary buds**, each of which forms in the angle (axil) where a leaf meets the stem. A **bud** is an undeveloped shoot that can develop further to produce another leaf, a phytomer, a flower, or a flowering stem. The axillary buds (also called lateral buds) are distinguished from the bud at the end of a stem or branch, which is called a **terminal bud**. If it becomes active, an axillary bud can develop into a new branch, which is an

extension of the shoot system. The arrangement of leaves along the stem (called phyllotaxy) is characteristic of plant species. Plant roots also have a modular construction. In the roots, each phytomer consists of a root segment between two branches.

phytomers In plants, the repeating modules that compose a shoot, each consisting of one or more leaves, attached to the stem at a node; an internode; and one or more axillary buds.

node [L. *nodus*: knob, knot] (1) In plants, a (sometimes enlarged) point on a stem where a leaf is or was attached. (2) A region at the anterior end of the primitive groove—the site of ingression of cells during gastrulation. In mammals and birds it serves a function similar to the dorsal lip of the blastopore in amphibians.

internode The region between two nodes of a plant stem.

axillary bud A bud that forms in the angle (axil) where a leaf meets a stem.

bud A protuberance on a stem that contains an undeveloped leaf, shoot, or flower.

terminal bud Growing point at the end of a plant stem or branch.

Most angiosperms are either monocots or eudicots

As you saw in [Key Concept 28.3](#), most angiosperms belong to one of two major clades.

Monocots are generally narrow-leaved flowering plants such as grasses, lilies, and orchids.

Eudicots are broad-leaved flowering plants such as soybeans, roses, sunflowers, and maples.

These two clades, which account for 97 percent of flowering plant species, differ in several basic characteristics, as shown in [Figure 33.2](#).

	Monocots	Eudicots
Embryos	 One cotyledon	 Two cotyledons
Stems	 Vascular tissue scattered	 Vascular tissue arranged in concentric circles
Leaf venation	 Veins usually parallel	 Veins form a network
Root system	 Fibrous (no main root)	 Taproot (main root) usually present
Flowers	 Floral organs usually in multiples of three	 Floral organs usually in multiples of four or five
Pollen	 Pollen grain with single furrow or pore	 Pollen grain with three furrows or pores

Figure 33.2 Comparing the Two Major Angiosperm Clades

Figure 33.2 Comparing the Two Major Angiosperm Clades There are several structural differences between monocots and eudicots.

Plants develop differently than animals

[Chapter 19](#) described four processes that govern development in all multicellular organisms: **determination** (the commitment of cells to their ultimate fates), **differentiation** (cell specialization), **morphogenesis** (the organization of cells into tissues and organs), and **growth** (increase in body size). In plants, these processes are influenced by four features: apical meristems, totipotency, vacuoles, and cell walls.

determination In development, the process whereby the fate of an embryonic cell or group of cells (e.g., to become epidermal cells or neurons) is set (becomes **determined**).

differentiation The process whereby originally similar cells follow different developmental pathways; the actual expression of determination.

morphogenesis (more' fo jen' e sis) [Gk. *morphe*: form + *genesis*: origin] The development of form; the overall consequence of determination, differentiation, and growth.

growth An increase in the size of the body and its organs by cell division and cell expansion.

MERISTEMS

Animals have stem cells to replace tissues lost through damage or apoptosis. Hundreds of millions of new cells are produced every day in the human body just to maintain itself. Plants, too, experience losses, both from herbivory and programmed events (such as leaf drop in the fall). Plant tissues and organs are generated in plant **meristems**: regions of undifferentiated cells where cell division occurs. **Apical meristems** are found at the tips of shoots and roots and allow plants to continue growing throughout their lives.

TOTIPOTENCY

During normal animal development, only the early embryonic cells are ***totipotent**: they can differentiate into any type of cell in the body. In contrast, some differentiated plant cells can dedifferentiate and become totipotent. This means that a plant can readily repair damage wrought by the environment or herbivores.

VACUOLES

Mature plant cells usually contain a single **central vacuole**, which may account for up to 90 percent of a cell's volume (see [Figure 5.13](#)). The vacuole is a watery sac containing solutes, including enzymes, amino acids, and sugars produced by photo-synthesis. Many of these solutes are pumped into the vacuole by transporter proteins located in the **tonoplast**, the vacuolar membrane. This active accumulation of solutes provides the osmotic force for water uptake into the vacuole, as we will explain in [Key Concept 34.1](#). As the vacuole expands, it exerts turgor pressure on the cell wall. Turgor pressure keeps plants upright and is essential for plant growth (see [Chapter 6](#)).

central vacuole In plant cells, a large organelle that stores the waste products of metabolism and maintains turgor.

tonoplast The membrane of the plant central vacuole.

CELL WALLS

Each plant cell is surrounded by a cell wall, which is interrupted by membrane-lined cytoplasmic channels called plasmodesmata (see [Key Concept 5.4](#)). This rigid extracellular matrix makes it impossible for cells to move from place to place, as they do in animal development. Instead, plant morphogenesis is controlled by the planes of cell division, which determine the direction in which a piece of tissue will grow ([Figure 33.3](#)). In addition, unequal cell division can occur when the cytoplasm contains differentiation signals that are localized in one part of a cell. Plant cell cytokinesis (the division of the cytoplasm) occurs along a cell plate laid down by membranous vesicles produced by the Golgi apparatus (see [Figure 11.12B](#)). Unlike animal cells, in which the location of cytokinesis depends on the location of the middle of the mitotic spindle, the location of the plant cell plate is determined earlier—as early as mitotic prophase.

Figure 33.3 Cytokinesis and Morphogenesis The plane of cell division can determine the growth pattern of a plant's organs, as in this section of a shoot.

Q: How do you think the plane of cell division is controlled?

One of the major ways that plants grow is by cell expansion. Some cells can increase in volume by 100,000 to 1,000,000 times! As a growing plant cell takes up water, it exerts turgor pressure on the cell wall, which resists cell expansion. For the cell to expand, the wall must expand too. Proteins appropriately called expansins reside in the cell wall and help loosen it by disrupting the noncovalent interactions between cellulose microfibrils and other polysaccharides in the cell wall. This is followed by the assembly of new polysaccharides and microfibrils, allowing the cell wall to grow:

The wall of a growing plant cell is called the [primary cell wall](#). When cell expansion stops,

some types of plant cells deposit one or more additional cellulosic layers to form a thick, rigid **secondary cell wall** that is internal to the primary cell wall:

primary cell wall In plant cells, a structure that forms at the middle lamella after cytokinesis, made up of cellulose microfibrils, hemicelluloses, and pectins. (Contrast with secondary cell wall.)

secondary cell wall A thick, cellulosic structure internal to the primary cell wall formed in some plant cells after cell expansion stops. (Contrast with primary cell wall.)

Secondary cell walls cannot expand. Instead they provide the mechanical support that allows some plants to produce large stems. The secondary wall contains layers of ordered cellulose microfibrils embedded in a remarkable substance called **lignin**. Lignin is a major component of wood; it is a complex, carbon-containing polymer. This matrix is strong, waterproof, and resistant to digestion by animals. After cellulose, lignin is the most abundant biological polymer on Earth, accounting for 20-35 percent of the dry weight of wood.

lignin A complex, hydrophobic polyphenolic polymer in plant cell walls that crosslinks other wall polymers, strengthening the walls, especially in wood.

Apical-basal polarity and radial symmetry are characteristics of the plant body

Two basic patterns are established early in plant embryogenesis (embryo formation) ([Figure 33.4](#));

- *The apical-basal axis*: the arrangement of cells and tissues along the main axis from root to shoot
- *The radial axis*: the concentric arrangement of the tissue systems (discussed in [Key Concept 33.2](#))

Figure 33.4 Two Patterns for Plant Morphogenesis The apical-basal pattern is the arrangement of cells and tissues along a main axis from root to shoot. The radial

pattern determines the concentric arrangement of tissues as organs grow in thickness.

Both axes are best understood in developmental terms. We will focus here on embryogenesis in *Arabidopsis thaliana*. As you have seen in previous chapters, *Arabidopsis* is a model eudicot that has been studied extensively by plant physiologists and geneticists. You can follow the steps in plant embryogenesis in [Figure 33.5](#).

Figure 33.5 Plant Embryogenesis The basic body plan of the model eudicot *Arabidopsis thaliana* is established in several steps. By the heart stage, the three tissue systems are established: the dermal (tan), ground (light green), and vascular (blue) tissue systems. These tissue systems are shown in the mature seed, which develops after many more stages.

Q: How do you think the differences between the apical and basal daughter cells are established?

The first step in the formation of an *Arabidopsis* embryo is a mitotic division of the zygote that gives rise to two daughter cells, an apical daughter cell and a basal daughter cell (see [Figure 33.5](#), Step 1). An asymmetrical plane of cell division results in an uneven distribution of cytoplasm between these two cells, and this determines their different fates. Signals in the smaller, apical daughter cell induce it to produce the embryo proper, while the larger basal daughter cell produces the **suspensor**, a structure that connects the developing embryo to the storage material (see [Figure 33.5](#), Step 2). This division not only establishes the apical-basal axis of the new plant but also determines its polarity (which end is the tip, or apex, and which is the base). A long, thin suspensor and a more spherical or globular embryo are distinguishable after just four mitotic divisions. The suspensor soon ceases to elongate.

suspensor In the embryos of seed plants, the stalk of cells that pushes the embryo into the endosperm and is a source of nutrient transport to the embryo.

In eudicots such as *Arabidopsis*, the initially globular embryo develops into the characteristic heart stage as the cotyledons start to grow (see [Figure 33.5](#), Step 3). Further elongation of the cotyledons and of the main axis of the embryo gives rise to the torpedo stage, during which some of the internal tissues begin to differentiate (see [Figure 33.5](#), Step 4). Between the cotyledons is the **shoot apical meristem**; at the other end of the axis is the **root apical meristem**. Each of these meristems contains undifferentiated cells that will continue to divide to give rise to the organs that will develop during the life of the plant.

shoot apical meristem Undifferentiated tissue at the apex of the shoot that gives rise to the organs of the shoot.

root apical meristem Undifferentiated tissue at the apex of the root that gives rise to the organs of the root.

As shown in Step 2 of [Figure 33.5](#), the plant embryo is first a sphere and later a cylinder. The root and stem retain this cylindrical shape throughout the plant's life. You can see this most easily in the trunk (mature stem) of a tree. By the end of embryogenesis, the radial symmetry of the plant has been established (see [Figure 33.4](#)). The embryonic plant contains three tissue systems, arranged concentrically, which will give rise to the tissues of the adult plant body. We will discuss these tissue systems in the next section.

33.1 recap

The vegetative plant body consists of a root system and a shoot system. The plant body is modular, made up of repeated units called phytomers. Plants are characterized by apical meristems, totipotency, vacuoles, and cell walls. The tissues of the plant body develop along two axes: the apical-basal axis (which establishes a polar pattern from root to shoot) and the radial axis (which establishes a concentric pattern of vascular, ground, and dermal tissue systems). Most angiosperms are either monocots or eudicots, which differ in several basic ways.

learning outcomes

You should be able to:

- Identify ways in which plants have overcome the problems of scarce resources and an inability to move.
- Analyze major differences in plant and animal development.
- Examine the process by which a zygote develops into an embryo with an apical-basal axis.

1. How do plants explore their environment for resources even though they cannot move?
2. Describe the primary ways that plant development differs from animal development.
3. Explain how apical-basal and radial patterns develop.
4. A mutant strain of *Arabidopsis* lacks apical-basal polarity in the embryo. What would you expect the phenotype of the plant to be?

In the next two sections we will look more closely at the unique characteristics of the plant body, by following its development from a zygote into an adult.

***connect the concepts** key concept 19.1 describes distinctive aspects and functions of totipotency in plants.

33.2 Plant Organs Are Made Up of Three Tissue Systems

By the end of embryogenesis, both the apical-basal and radial axes have been established. Unlike complex animals that can have dozens of different tissues (for example, in humans there are three kinds of muscle tissue alone), plants have just three major tissue systems, each of which has specialized cells.

focus your learning

Ground tissue forms most of the plant body and includes parenchyma, collenchyma, and sclerenchyma. The dermal and vascular systems have parenchyma and sclerenchyma.

Vascular tissue consists of xylem and phloem, which are the plant's transport system.

As **Focus: Key Figure 33.6** illustrates, the three major plant tissue systems develop in a radial pattern in the embryo, establishing a concentric arrangement of dermal, ground, and vascular tissues. From these tissue systems will arise the roots, stems, and leaves of the adult vegetative plant body.

focus: key figure

Figure 36.6 Three Tissue Systems Extend throughout the Plant Body The arrangement shown here is typical of eudicots, but the three tissue systems are continuous in the bodies of all vascular plants.

Q: What is a major difference between cells in the ground tissue in the leaf compared to the root?

The dermal tissue system forms the outer covering of a plant

During plant development, the **dermal tissue system** develops in a plant's outermost layer of

cells, called its **epidermis**. The stems and roots of woody plants develop a dermal tissue called **periderm**.

dermal tissue system The system of cells that forms the outer covering of a plant, consisting of epidermis in the young plant and periderm in a plant with extensive secondary growth. (Contrast with ground tissue system, vascular tissue system.)

epidermis [Gk. *epi*: over + *derma*: skin] In plants and animals, the outermost cell layers. (Only one cell layer thick in plants.)

periderm The outer tissue of the secondary plant body, consisting primarily of cork.

The epidermis grows to cover the expanding plant body. The cells of the epidermis are initially small and round and usually have a small central vacuole or none at all. Once cell division ceases in the epidermis of an organ, the epidermal cells expand. Some epidermal cells differentiate to form one of three specialized structures, about which you'll learn more later:

- . Stomatal guard cells, which form stomata (pores) for gas exchange in leaves
- . Trichomes, or leaf hairs, which provide protection against insects and damaging solar radiation, as well as secrete oils (such as those produced by mints)
- . Root hairs, which greatly increase root surface area, thus providing more surface for the uptake of water and mineral nutrients

The aboveground epidermal cells secrete a protective extracellular layer called a **cuticle**. The cuticle is made up of cutin (a polymer composed of long chains of fatty acids), a complex mixture of waxes, and cell wall polysaccharides. The cuticle limits water loss, reflects potentially damaging solar radiation, and serves as a barrier against pathogens.

cuticle (1) In plants, a waxy layer on the outer body surface that retards water loss. (2) In ecdysozoans, an outer body covering that provides protection and support and is periodically molted.

The ground tissue system makes up most of the plant body

Virtually all the tissue lying between the dermal tissue and the vascular tissue in both shoots and roots is part of the **ground tissue system**. Therefore the ground tissues make up most of the plant body. Three main cell types are commonly seen in the ground tissue system: parenchyma, collenchyma, and sclerenchyma. Ground cell types are generally distinguished by the nature of their cell walls.

ground tissue system Those parts of the plant body not included in the dermal or vascular tissue systems. Ground tissues function in storage, photosynthesis, and support.

PARENCHYMA The most common cell type in plants is the **parenchyma** cell (**Figure 33.7A**). Parenchyma cells often have large vacuoles and thin walls consisting only of a primary wall and the shared middle lamella. The **middle lamella** is a layer of pectin that cements adjacent plant cells together (see **Figure 5.21**). Parenchyma cells play important roles in photosynthesis (mainly in the leaves); proteins, starch, fats, or oils may be stored in parenchyma cells of the seeds and/or roots. Many retain the capacity to divide, as when a wound results in cell

proliferation.

parenchyma (pair eng' kyma) A plant tissue composed of relatively unspecialized cells without secondary walls. (Contrast with collenchyma, sclerenchyma.)

middle lamella (la mell' ah) [L. *lamina*: thin sheet] A layer of polysaccharides that separates plant cells; a shared middle lamella lies outside the primary walls of the two cells.

(A) Parenchyma

(B) Collenchyma

(C) Sclerenchyma

Figure 33.7 Ground Tissue Cell Types (A) Parenchyma cells in the petiole of *Coleus*. Note the thin, uniform cell walls. (B) Collenchyma cells make up the outer cell layers of this spinach leaf vein. Their walls are thick at the corners of the cells and thin elsewhere. (C) The two types of sclerenchyma cells. Left: Fibers in a sunflower stem (*Helianthus*). The thick secondary walls are stained red. Right: Sclereids. The extremely thick secondary walls of sclereids are laid down in layers. They provide support and a hard texture to structures such as nuts and seeds.

COLLENCHYMA

Collenchyma cells resemble parenchyma cells that have been modified to provide flexible support. They are generally elongated, and their primary walls are characteristically thick at the corners of the cells (Figure 33.7B). In these cells the primary wall thickens in part because of the deposition of pectins, but no secondary wall forms. Collenchyma cells provide support to leaf petioles, nonwoody stems, and growing organs. Tissue made of collenchyma cells is flexible, permitting stems and petioles to sway in the wind without snapping. The familiar "strings" in celery consist primarily of collenchyma cells.

SCLERENCHYMA

There are two types of sclerenchyma cells: elongated **fibers** and variously shaped **sclereids** (Figure 33.7C). Both cell types have thickened secondary walls that enable their major function: support. Many sclerenchyma cells undergo programmed cell death (apoptosis; see Key Concept 11.6) after developing the lignified secondary walls, and thus perform their supporting function

when dead. Fibers are often organized into bundles and provide relatively rigid support to wood, bark, and other parts of the plant. Sclereids may pack together densely, as in a nut's shell or in some seed coats. Isolated clumps of sclereids, called stone cells, occur in pears and some other fruits and give them their characteristic gritty texture.

fiber In angiosperms, an elongated, tapering sclerenchyma cell, usually with a thick cell wall, that serves a support function in xylem. (See *also* muscle fiber.)

sclereid One of the principle types of cells in sclerenchyma.

The vascular tissue system develops into the plant's transport system

The **vascular tissue system** is the plant's plumbing, or transport system—the distinguishing feature of vascular plants. Its two constituent tissues, the xylem and phloem, distribute materials throughout the plant. The **xylem** distributes water and mineral ions taken up by the roots to all the cells of the stems and leaves. **Phloem** performs a variety of functions, including transport, support, and storage. The phloem plays a particularly critical role in supplying the energy-rich molecules and chemical building blocks needed by all living cells of the plant body. The phloem transports carbohydrates away from the sites of production, which are called **sources** (primarily leaves), and delivers them to sites of utilization or storage, called **sinks**. Sinks include growing tissues, storage organs, and developing flowers

vascular tissue system The transport system of a vascular plant, consisting primarily of xylem and phloem. (Contrast with dermal tissue system, ground tissue system.)

xylem (zy' lum) [Gk. *xylon*: wood] In vascular plants, the tissue that conducts water and minerals; xylem consists, in various plants, of tracheids, vessel elements, fibers, and other highly specialized cells.

phloem (flo' um) [Gk. *phloos*: bark] In vascular plants, the vascular tissue that transports sugars and other solutes from sources to sinks.

source In plants, any organ that exports the products of photosynthesis in excess of its own needs, such as a mature leaf or storage organ. (Contrast with sink.)

sink In plants, any organ that imports the products of photosynthesis, such as roots, developing fruits, and immature leaves. (Contrast with source.)

Let's take a closer look at the structures of the diverse cell types that make up these vascular tissues. In [Chapter 34](#) you'll see how they transport water and materials throughout the plant body.

XYLEM TISSUE

Xylem tissue contains conducting cells called **tracheary elements**, which have secondary cell walls and undergo apoptosis before assuming their function of transporting water and dissolved minerals. There are two types of tracheary elements: tracheids and vessel elements. The spindle-shaped **tracheids** ([Figure 33.8A](#)) are evolutionarily more ancient than vessel elements and are the major cell type in the wood of gymnosperms (major groups of gymnosperms are covered in [Key Concept 28.2](#)). When tracheids die, their internal components disintegrate and pits remain between the cells. Pits are cavities in secondary walls, arranged such that pits of adjacent cells are situated across from each other. Water and minerals move rapidly from one cell to another because these substances need to cross only one thin extracellular barrier, the primary cell wall.

tracheary element Either of two types of xylem cells—tracheids and vessel elements—that undergo apoptosis before assuming their transport function.

tracheid (tray' kee id) A type of tracheary element found in the xylem of nearly all vascular plants, characterized by tapering ends and walls that are pitted but not perforated. (Contrast with vessel element.)

(A) Tracheids

(B) Vessel elements

(C) Sieve tube elements

Figure 33.8 Vascular Tissue Cell Types (A, B) Tracheary elements: (A) Tracheids in pinewood. The thick secondary walls are stained dark red. (B) Vessel elements in the stem of a squash. The secondary walls are stained red; note the different patterns of thickening, including rings and spirals. (C) Sieve tube elements and companion cells in the stem of a cucumber.

Flowering plants have evolved a water-conducting system made up of vessels, which are

formed from individual cells called [vessel elements](#). These cells are laid down end-to-end. Like tracheids, vessel elements have pits in their cell walls, but their pits are generally larger in diameter than those of tracheids. Before they undergo apoptosis, the end walls of vessel elements partially break down, forming a continuous hollow tube that functions as an open pipeline for water conduction ([Figure 33.8B](#)). In the course of angiosperm evolution, vessel elements have become shorter and wider, and their end walls have become less oblique and less obstructed. These adaptations have presumably increased the efficiency of water transport through the vessels. The xylem of many angiosperms includes both tracheids and vessels.

vessel element A type of tracheary element with perforated end walls; found only in angiosperms. (Contrast with tracheid.)

PHLOEM TISSUE

The transport cells of the phloem, unlike those of the mature xylem, are living cells. In flowering plants the characteristic cells of the phloem are called [sieve tube elements](#) ([Figure 33.8C](#)). Like vessel elements, these cells meet end-to-end. They form long sieve tubes, which transport carbohydrates and many other materials from their sources (usually leaves) to tissues that consume or store them (for example, roots).

sieve tube element The characteristic cell of the phloem in angiosperms, which contains cytoplasm but relatively few organelles, and whose end walls (**sieve plates**) contain pores that form connections with neighboring cells.

Whereas the end walls of vessel elements break down to facilitate flow through the vessels, the end walls of sieve tube elements form tunnels through which carbohydrates and other needed substances flow. The end walls of sieve tube elements are called sieve plates. Although the sieve tube elements remain alive, some of their components, including the nucleus, ribosomes, and vacuole, break down during development. The sieve tube elements are, however, closely connected via plasmodesmata to [companion cells](#) — specialized parenchyma cells that retain all their organelles and function as "life support systems" for the sieve tube elements.

companion cell In angiosperms, a specialized cell found adjacent to a sieve tube element.

33.2 recap

The three concentric tissue systems of the plant embryo—dermal, ground, and vascular—give rise to the tissues and organs of the adult plant. These tissue systems have unique combinations of specialized cells that carry out the various functions necessary for plant life.

learning outcomes

You should be able to:

- List and discuss the importance of the various functions of parenchyma.
- Define cell characteristics that make collenchyma useful as plant support structures.
- Compare collenchyma and sclerenchyma in terms of their ability to provide support to

plants.

- Describe the water-conducting elements in plants, and compare these elements in gymnosperms and angiosperms.
-

1. Create a table comparing the three types of ground tissue cell types in terms of their structure and function.
 2. What structural differences make tissues consisting of collenchyma cells more flexible than those consisting primarily of sclerenchyma cells?
 3. Describe the differences between tracheids and vessel elements.
-

After the plant embryo has formed, it is encased in a seed coat and is ready to germinate. We will discuss aspects of seed germination in the chapters that follow. For now, let's consider the processes by which the embryo grows into a mature plant.

33.3 Meristems Build a Continuously Growing Plant

As noted earlier, plants and animals develop and function differently. While animals use their mobility to look for food, plants are sessile (rooted in one place) and instead grow toward scarce resources, both above (shoots toward the sun) and below the ground (roots toward water and minerals).

focus your learning

Growth in plants can be either determinate or indeterminate, depending on the organ structure.

Growth in terms of cell numbers occurs at meristems.

Different apical meristems are where growth in cell numbers occurs and gives rise to leaves, stems, flowers, and roots.

At the root meristem, zones of cell division, elongation, and maturation (differentiation) form the tissues of the root and root cap.

The root consists of several tissue layers outside of the inner vascular tissues. These tissues have different arrangements in eudicot and monocot roots.

Secondary growth in eudicots causes increase in diameter and forms wood and bark.

In most animals, growth is **determinate**: they stop growing when they reach the adult state. Some plant organs, such as leaves, flowers, and fruits, also show determinate growth. But shoots and roots keep growing; such open-ended growth is **indeterminate**.

determinate growth A growth pattern in which the growth of an organism or organ ceases when an adult state is reached; characteristic of most animals and some plant organs. (Contrast with indeterminate growth.)

indeterminate growth An open-ended growth pattern in which an organism or organ continues to grow as long as it lives; characteristic of some animals and of plant shoots and roots. (Contrast with determinate growth.)

How do plants increase in size?

Plant growth can occur in either of two ways:

- **Primary growth** is characterized by cell division followed by cell enlargement. Primary growth results in the proliferation and lengthening of shoots and roots. All seed plants have a primary plant body, which consists of all the nonwoody parts of the plant. Many herbaceous plants consist entirely of a primary plant body.

primary growth In plants, growth that is characterized by the lengthening of roots and shoots and by the proliferation of new roots and shoots through branching. (Contrast with secondary growth.)

- **Secondary growth** increases plant thickness. Woody plants, such as trees and shrubs, have a secondary plant body consisting of wood and bark. As the tissues of the secondary plant body are laid down, the stems and roots thicken.

secondary growth In plants, growth that contributes to an increase in girth. (Contrast with primary growth.)

Meristems generate the plant body

Meristems are localized regions of undifferentiated cells that are the sources of all new growth in the adult plant. Even before seed germination, the plant embryo has two meristems: a shoot apical meristem near the end of the embryonic shoot, and a root apical meristem at the end of the embryonic root (see [Figure 33.5](#)).

Meristematic cells are small and closely packed, with very small vacuoles and thin primary cell walls. The cells that perpetuate the meristems, called **initials**, are comparable to animal stem cells (discussed in [Key Concept 19.1](#)). When the initials divide, some of the daughter cells develop into new initials, and some differentiate into more specialized cells.

initials Cells that perpetuate plant meristems, comparable to animal stem cells. When an initial divides, one daughter cell develops into another initial, while the other differentiates into a more specialized cell.

Several types of meristem contribute to the growth and development of the adult plant:

Apical meristems in the root and shoot ([Figure 33.9](#)) orchestrate primary growth, ultimately giving rise to every cell in the primary plant body.

Figure 33.9 Apical and Lateral Meristems Root and shoot apical meristems produce the primary plant body, lengthening it; lateral meristems produce the secondary plant body, thickening it.

Media Clip 33.1 **Rapid Growth of Brambles** www.Life11e.com/mc33.1

When the initials of apical meristems divide, some of their daughter cells differentiate and become the **primary meristems**. Three kinds of primary meristem (see below) give rise to the three major tissue systems (dermal, ground, and vascular) that we described in [Key Concept 33.2](#).

primary meristem Meristem that produces the tissues of the primary plant body.

Lateral meristems (also called secondary meristems) orchestrate secondary growth (see [Figure 33.9](#)). Two lateral meristems, vascular cambium and cork cambium, contribute to the secondary plant body.

lateral meristem Either of the two meristems, the vascular cambium and the cork cambium, that give rise to a plant's secondary growth.

Indeterminate primary growth originates in apical meristems

Because apical meristems can perpetuate themselves indefinitely, a stem or root can continue to lengthen and grow indefinitely; in other words, growth of the plant body as a whole is indeterminate. All plant organs arise ultimately from cell divisions in apical meristems, followed by cell expansion and differentiation. Several types of apical meristems play roles in organ formation:

Shoot apical meristems supply the cells for new leaves and stems. In addition to the main stem of the plant, each branch has its own shoot apical meristem. Shoot apical meristems are also called **vegetative meristems**, because they give rise to vegetative tissues (leaves, stems, and roots).

vegetative meristem An apical meristem that produces leaves.

When the plant is ready to flower, one or more of its shoot apical meristems are transformed into **inflorescence meristems**, and these in turn develop **floral meristems**. ([Chapter 37](#) is dedicated to the reproduction of flowering plants; inflorescence and floral meristems are discussed in [Key Concept 37.2](#).)

inflorescence meristem A meristem that produces floral meristems as well as other small leafy structures (bracts).

floral meristem In angiosperms, a meristem that forms the floral organs (sepals, petals, stamens, and carpels).

Root apical meristems supply the cells that extend roots, enabling the plant to penetrate and explore the soil for water and minerals. Each type of root (i.e., the taproot, a lateral root, or an adventitious root; see below) has its own root apical meristem.

Apical meristems in both the shoot and the root give rise to a set of primary meristems, which produce the tissues of the primary plant body. From the outside to the inside of the shoot or root,

the primary meristems are the **protoderm**, the **ground meristem**, and the **procambium** (see [Figure 33.10A](#)). These meristems, in turn, give rise to the three tissue systems:

protoderm Primary meristem that gives rise to the plant epidermis.

ground meristem That part of an apical meristem that gives rise to the ground tissue system of the primary plant body.

procambium Primary meristem that produces the vascular tissue.

(A) Root anatomy

(B) Roots hairs (SEM)

Figure 33.10 Tissues and Regions of the Root Tip (A) Extensive cell division creates the complex structure of the root. (B) Root hairs, seen with a scanning

electron microscope (SEM).

Media Clip 33.2 **Cell Expansion in Root Hairs** www.Life11e.com/mc33.2

Because meristems can continue to produce new organs throughout the lifetime of the plant, the plant body is much more variable in form than the typical animal body, which produces each organ only once.

Let's look more closely at how the root apical meristem produces the root system.

The root apical meristem gives rise to the root cap and the root primary meristems

The root apical meristem produces all the cells that contribute to the growth and development of the root ([Figure 33.10A](#)). Some of the daughter cells from the apical (tip) end of the root apical meristem contribute to a [root cap](#), which protects the delicate growing region of the root as it pushes through the soil. The root cap secretes a mucopolysaccharide (slime) that acts as a lubricant. Even so, the cells of the root cap are often damaged or scraped away and must therefore be replaced constantly. The root cap is also the structure that detects the pull of gravity and thus controls the downward growth of roots.

root cap A thimble-shaped mass of cells, produced by the root apical meristem, that protects the meristem; the organ that perceives the gravitational stimulus in root gravitropism.

In the middle of the root apical meristem is a quiescent center, in which cell divisions are rare. The quiescent center cells may be in G1 phase of the cell cycle for 10 days and prevent the surrounding meristem cells from differentiating. The daughter cells produced above the quiescent center (that is, away from the root cap) become the three primary meristems.

The apical and primary meristems constitute the [zone of cell division](#), the source of all the cells of the root's primary tissues. Just above this zone is the [zone of cell elongation](#), where the newly formed cells are elongating and thus pushing the root farther into the soil. Above that zone is the [zone of maturation](#), where the cells are differentiating, taking on specialized forms and functions. These three zones grade imperceptibly into one another; there is no abrupt border separating them.

zone of cell division The apical and primary meristems of a plant root; the source of all cells of the root's primary tissues.

zone of cell elongation The part of a plant root, generally above the zone of cell division, where cells are expanding (growing), primarily in the longitudinal direction.

zone of maturation The part of a plant root, generally above the zone of cell elongation, where cells are differentiating.

The products of the root's primary meristems become root tissues

The products of the three primary meristems (the protoderm, ground meristem, and procambium) are the tissue systems of the mature root. The differing arrangement of the three tissue systems in the roots of eudicots and monocots is one of the ways in which the two clades are distinguished ([Figure 33.11](#)).

(A) Eudicot root

(B) Monocot root

Figure 33.11 Products of the Roots Primary Meristems The protoderm gives rise to the outermost layer (epidermis). The ground meristem produces the cortex, the innermost layer of which is the endodermis. The primary vascular tissues of the root are found in the stele, which is the product of the procambium. The arrangement of tissues in the stele differs in the roots of (A) eudicots and (B) monocots. The photomicrographs show cross sections of the stele of a representative eudicot (the buttercup, *Ranunculus*) and a representative monocot (corn, *Zea mays*), showing the arrangement of the primary root tissues.

 Activity 33.1 **Eudicot Root** www.Life11e.com/ac33.1

 Activity 33.2 **Monocot Root** www.Life11e.com/ac33.2

The protoderm produces the epidermis, the outer layer of cells that is adapted for protection of the root and absorption of mineral ions and water. Many of the epidermal cells produce long, delicate **root hairs**, which vastly increase the surface area of the root (**Figure 33.10B**). Root hairs grow out among the soil particles, probing nooks and crannies and taking up water and minerals.

root hair A long, thin process from a root epidermal cell that absorbs water and minerals from the soil solution.

The **cortex** is a region of ground tissue produced internal to the epidermis by the ground meristem. The cells of the multi-layered cortex have various functions, including storage.

cortex [L. *cortex*: covering, rind] (1) In plants, the tissue between the epidermis and the vascular tissue of a stem or root. (2) In animals, the outer tissue of certain organs, such as the adrenal gland (adrenal cortex) and the brain (cerebral cortex).

The **endodermis** is the innermost layer of the cortex. Unlike other cortical cells, the

endodermal cells contain a waterproof substance called suberin in their primary cell walls. The suberin forms a cylindrical ring around the inside of the endodermis, which allows the endodermal cells to control the movement of water and dissolved mineral ions into and out of the vascular tissue system.

endodermis In plants, a specialized cell layer marking the inside of the cortex in roots and some stems. Frequently a barrier to free diffusion of solutes.

Inner to the endodermis is the vascular cylinder, or **stele**, produced by the procambium. The stele consists of three tissues: pericycle, xylem, and phloem. The **pericycle** consists of one or more layers of relatively undifferentiated cells. It has three important functions: (1) It is the tissue within which lateral roots arise (**Figure 33.12**). (2) It can contribute to secondary growth by giving rise to lateral meristems that thicken the root. (3) Its cells contain membrane transport proteins that export nutrient ions into the cells of the xylem.

stele (steel) [Gk. pillar] The central cylinder of vascular tissue in a plant stem.

pericycle [Gk. *peri*: around + *kyklos*: ring or circle] In plant roots, tissue just within the endodermis, but outside of the root vascular tissue. Meristematic activity of pericycle cells produces lateral root primordia.

Figure 33.12 Lateral Root Anatomy SEM of the tip of a lateral root in a willow tree. Cells in the pericycle divide and the products differentiate, forming the tissues of a lateral root.

Q: How does totipotency relate to lateral root formation?

At the very center of the root of a eudicot lies the xylem. Seen in cross section, it typically has the shape of a star with a variable number of points (see **Figure 33.11A**). Between the points are bundles of phloem. In monocots, a region of parenchyma cells called the **pith** typically lies in the center of the root, surrounded by xylem and phloem (see **Figure 33.11B**). Pith, which often stores carbohydrate reserves, is also found in the stems of both eudicots and monocots. Strips of pith of the stem of the papyrus plant *Cyperus papyrus* can be glued together and used to make a paperlike substance called by its species name. Papyrus dates from earlier than 2500

B.O.E. in Egypt, and was the writing surface of choice until about 300 C.E., when parchment from animal skins replaced it.

pith In plants, relatively unspecialized tissue found within a cylinder of vascular tissue.

The root system anchors the plant and takes up water and dissolved minerals

Water and minerals enter most plants through the root system, which is located in the soil. Because light does not penetrate the soil, roots typically lack the capacity for photosynthesis. Although hidden from view, the root system is often larger than the visible shoot system. For example, the root system of a 4-month-old winter rye plant (*Secale cereale*) was found to be 130 times longer in total than the shoot system, with almost 13 million branches that had a cumulative length of more than 500 kilometers!

Angiosperm root systems develop from the embryonic root, called the **radicle**. From this common starting point, the root systems of monocots and eudicots develop differently. Following seed germination, the radicle of most eudicots develops as a primary root called the **taproot**, which extends downward by tip growth and outward by initiating **lateral roots**. The taproot and the lateral roots form a **taproot system**, which can take a variety of forms. For example, the taproot itself often functions as a nutrient storage organ, as in carrots (*Daucus carota*), sugar beets (*Beta vulgaris*), and sweet potato (*Ipomoea batatas*) (**Figure 33.13A**).

radicle An embryonic root.

taproot The largest plant root from which other roots sprout laterally.

lateral root A root extending outward from the taproot in a taproot system; typical of eudicots.

taproot system A root system typical of eudicots consisting of a primary root (taproot) that extends downward by tip growth and outward by initiating lateral roots. (Contrast with fibrous root system.)

(A) Taproots

(B) Fibrous root system

(C) Prop roots

Figure 33.13 Root Systems of Eudicots and Monocots A) The taproot systems of eudi-cots, such as carrots and sugar beets, contrast with **(B)** the fibrous root system of a leek and **(C)** the adventitious prop roots of corn.

In contrast, the primary root of monocots (and some eudicots) is short-lived. Because they originate from the stem at ground level or just below, the roots of a typical monocot are called **adventitious** (“arriving from outside”) **roots**, and they form a **fibrous root system** composed of numerous thin roots that are all roughly equal in length (**Figure 33.13B**). Many fibrous root systems have large surface areas for the absorption of water and minerals. A fibrous root system clings to soil very well. The fibrous root systems of grasses, for example, may protect steep hillsides where runoff from rain would otherwise cause erosion.

adventitious roots (ad ven ti’ shus) [L. *adventitius*: arriving from outside] Roots originating from the stem at ground level or below; typical of the fibrous root system of monocots.

root The organ responsible for anchoring the plant in the soil, absorbing water and minerals, and producing certain hormones. Some roots are storage organs.

fibrous root system A root system typical of monocots composed of numerous thin adventitious roots that are all roughly equal in diameter. (Contrast with taproot system.)

In some plants—corn, banyan, and pandanus trees, for example— adventitious roots grow

down from above the ground and function as props to help support the shoot system ([Figure 33.13C](#)). These **prop roots** have evolved for different reasons in different species. For example, some monocots may develop prop roots because they are unable to support aboveground growth through the thickening of their stems. Pandanus trees often grow near coastal beaches, where their prop roots help provide support in very sandy soils. Banyans begin life as epiphytes (plants that grow on other plants) and then develop woody prop roots, which enable them to grow into huge trees.

prop roots Adventitious roots in some monocots that function as supports for the shoot.

The products of the stem's primary meristems become stem tissues

Now let's turn to the shoot, which comprises the stem and leaves. As seen in [Figure 33.1](#), shoots and roots are composed of repeating modules called phytomers. A phytomer in the shoot system consists of a node with its attached leaf or leaves, the internode below the node, and axillary buds, each of which forms in the angle between a leaf and the stem. Shoots grow by adding new phytomers. Initially these form only on the primary stem of the plant, but if an axillary bud develops into a branch, it does so by producing new phytomers. The new phytomers originate from cells in the shoot apical meristems, which are present in the terminal buds of each branch and the main stem (see [Figure 33.9](#)).

The shoot apical meristem, like the root apical meristem, forms three primary meristems: protoderm, ground meristem, and procambium. These primary meristems, in turn, give rise to the three shoot tissue systems.

As the shoot grows and extends, bulges called **leaf primordia** develop on the sides of the shoot apical meristem at regular intervals (see [Figure 33.9](#)). These primordia are made up of primary meristematic tissues, which go on to develop into the mature tissues of the leaf. In addition, bud primordia form at the bases of the leaf primordia. These have the potential to become new apical meristems and initiate new shoots. The sites where leaf primordia form become nodes on the developing stem. The regions between the nodes (the internodes) lengthen initially via cell division in the primary meristematic tissues, and later by cell elongation in the mature stem tissues. The growing stem has no protective structure analogous to the root cap, but the leaf primordia can act as a protective covering for the shoot apical meristem.

leaf primordium (plural: primordia) An outgrowth on the side of the shoot apical meristem that will eventually develop into a leaf.

The vascular systems of stems differ from those of roots. In a root, the vascular tissue lies deep in the interior, with the xylem at or near the center (see [Figure 33.11](#)). The vascular tissue of a young stem, however, is divided into discrete **vascular bundles** ([Figure 33.14](#)). Each vascular bundle contains both xylem and phloem. In eudicots the vascular bundles generally form a ring, whereas in monocots they are scattered throughout the stem.

vascular bundle In vascular plants, a strand of vascular tissue, including xylem and phloem as well as thick-walled fibers.

Figure 33.14 Vascular Bundles in Stems (A) In herbaceous eudicot stems, the vascular bundles are arranged in a cylinder, with pith in the center and the cortex outside the cylinder. (B) A scattered arrangement of vascular bundles is typical of monocot stems.

▶ Activity 33.3 Monocot Root www.Life11e.com/ac33.3

▶ Activity 33.4 Monocot Root www.Life11e.com/ac33.4

In addition to the vascular tissues, the stem contains other important storage and supportive tissues. In eudicots the pith lies inside the ring of vascular bundles and also extends between them, forming regions called pith rays. To the outside lies the cortex, which may contain supportive collenchyma cells with thickened walls. The pith and cortex constitute the ground tissue system of the stem. The outermost cell layer of the young stem is the epidermis.

The stem supports leaves and flowers but can have other roles

The main role of stems is to elevate and support the photosynthetic organs (leaves) as well as the reproductive organs (flowers). But in some plants the stem does other things for the plant. For instance, the potato tuber that we eat comes from the ground but is not a root; it's an underground stem that acts as a storage organ for the plant.

The "eyes" of a potato are depressions containing axillary buds—in other words, a sprouting potato is just a branching stem ([Figure 33.15A](#)). Many desert plants have enlarged, water-retaining stems ([Figure 33.15B](#)). The runners of strawberry plants are horizontal stems that develop adventitious roots some distance from the main stem ([Figure 33.15C](#)); if the links between the rooted portions are broken, independent plants can develop on each side of the break—a form of vegetative (asexual) reproduction (see [Key Concept 37.3](#)).

(A)

(B)

(C)

Figure 33.15 Modified Stems (A) A potato is a modified stem called a tuber; the sprouts that grow from its "eyes" are shoots, not roots. **(B)** The stem of this barrel cactus is enlarged to store water. Its highly modified leaves serve as thorny spines. Most of this plant's photosynthesis occurs in the stem. **(C)** The runners of strawberry are horizontal stems that produce roots and shoots at intervals. Rooted portions of the plant can live independently if the runner is cut.

Leaves are determinate organs produced by shoot apical meristems

For most of its life, a plant produces leaves from apical meristems. Leaves originate from the edges of the apical meristem as initial cells that differentiate into leaf primordia. Leaves differ from stems in two important ways:

- . Unlike the growth of the stem, which is indeterminate, the growth of a leaf is determinate.
- . Whereas the tissues of the stem are arranged in a radial pattern, the ***leaf**, as a flat organ, has a distinct top side and bottom side.

Leaf anatomy is beautifully adapted to carry out photosynthesis, and to support that process by exchanging the gases O_2 and CO_2 with the environment, while at the same time limiting evaporative water loss([Figure 33.16](#)). Its extensive vascular system supplies the leaf with water and mineral nutrients and exports the products of photosynthesis to the rest of the plant. [Figure 33.16A](#) shows a typical eudicot leaf in three dimensions. The photosynthetic parenchyma tissue in leaves is the **mesophyll** (which means "middle of the leaf"). Most eudicot leaves have two zones of mesophyll: an upper layer of elongated cells called the palisade mesophyll, and a lower layer of irregularly shaped cells called the spongy mesophyll. Within the spongy mesophyll is a great deal of air space through which CO_2 can diffuse to photosynthesizing cells.

mesophyll (mez' uh fill) [Gk. *mesos*: middle + *phyllon*: leaf] Chloroplast-containing, photosynthetic cells in the interior of leaves.

(B)

(C)

Figure 33.16 The Eudicot Leaf (A) This three-dimensional diagram shows a section of a eudicot leaf. (B) The network of fine veins in this maple leaf carries water to the mesophyll cells and carries photosynthetic products away from them. (C) Carbon dioxide enters the leaf through stomata like this one on the epidermis of a eudicot leaf. Trichomes are epidermal hairs that can break up airflow, reducing water loss from the leaf and repel water so that gas exchange can take place through the stomata.

 Activity 33.5 **Eudicot Leaf** www.Life11e.com/ac33.5

Vascular tissue branches extensively throughout the leaf, forming a network of veins (see [Figure 33.16B](#)). Veins extend to within a few cell diameters of all the cells of the leaf by the xylem, ensuring that the mesophyll cells are well supplied with water and minerals. The products of photosynthesis are loaded into the veins for export to the rest of the plant. In addition to photosynthetic products, leaves make defensive molecules such as those you learned about in the opening investigation that produce cyanide in cassava. **Investigating Life: Understanding the Synthesis and Transport of Cyanogenic Glycosides** describes how it was determined that leaves produce these chemicals.

The epidermis covers the entire surface of the leaf. The epidermal cells secrete a waxy cuticle that is impermeable to water. Although this impermeability prevents excessive water loss, it also poses a problem: while the epidermis keeps water in the leaf, it also keeps out CO₂—the other raw material of photosynthesis.

The problem of balancing water retention and carbon dioxide availability is solved by guard cells, a system we'll examine in detail ([Key Concept 34.3](#)). Stomatal guard cells are modified epidermal cells that can change their shape, thereby opening or closing pores called **stomata** (singular *stoma*). The stomata serve as passageways between the environment and the leaf's interior (see [Figure 33.16C](#)). When the stomata are open, carbon dioxide can enter and oxygen can leave, but water can also be lost.

Many stems and roots undergo secondary growth

As you have seen, the roots and stems of some eudicots develop a secondary plant body, the tissues of which include wood and bark. These tissues are derived by secondary growth from the two lateral meristems:

The **vascular cambium** is a cylindrical layer of tissue consisting predominantly of elongated cells that divide frequently. It supplies the cells of the secondary xylem and secondary phloem, which eventually become wood and bark, respectively.

vascular cambium (kam' bee um) [L. *cambiare*: to exchange] In plants, a lateral meristem that gives rise to secondary xylem and phloem.

The **cork cambium** produces mainly waxy-walled protective cells. It supplies some of the cells that become bark.

cork cambium [L. *cambiare*: to exchange] In plants, a lateral meristem that produces secondary growth, mainly in the form of waxy-walled protective cells, including some of the cells that become bark.

Understanding the Synthesis and Transport of Cyanogenic Glycosides

experiment

Original Paper: Jørgensen, K. et al. 2005. Cassava plants with a depleted cyanogenic glycoside content in leaves and tubers. Distribution of cyanogenic glycosides, their site of synthesis and transport and blockage of biosynthesis by RNA interference technology. *Plant Physiology* 139: 363–374.

As described in the chapter opening, cassava is the most important root crop in the world. Its use as food is challenging, because the plant produces molecules that can be transformed into toxic cyanide when the tissues are disrupted. These cyanogenic glycosides (CGs) are important in defending the plant against animals that eat it, including humans. For the millions of people who eat cassava, careful processing is needed to avoid poisoning. Unfortunately, the processing methods lower the overall nutritional value of the food. Understanding how CGs are made and end up in the fleshy root is an important step in possibly using genetics to produce a crop that does not make CGs. At the Royal Veterinary and Agricultural University in Copenhagen, a team led by Birger Møller investigated the synthesis and transport of CGs in cassava plants.

HYPOTHESIS Molecules that produce cyanide in the cassava are made in the leaves and transported to the underground root.

METHOD

RESULTS

Region	Relative CG concentration	Region	Relative CG concentration
Shoot apex	Moderate	Fifth leaf	High
First petiole	High	Stem above cut	Moderate
Third leaf	Low	Stem below cut	Very Low
Third petiole	Low		

CONCLUSION Cyanogenic glycosides are made in leaves and are transported through petioles to the stem, from which they are transported to the root.

work with the data

QUESTIONS

1. Cyanogenic glycosides in plant organs were measured in an intact stem of a cassava plant and in one in which the phloem had been cut below the fifth leaf. The results are shown in the graphs. What can you conclude about the source of CG?

2. When a stem is girdled, it is cut carefully so that the epidermal, cortical, and outer vascular tissues (phloem) are removed. Using intact plants, the biologists girdled the stem of a cassava plant. After 2 days, they measured CG in various regions on the stem. The results for CG levels after girdling between the fifth and sixth nodes are shown in the table. What can you conclude about the source and transport of CG? Why was the level in the sixth leaf (below the girdle) so high?

Region	CG level (μmol)
Fifth leaf	59
Stem above cut	15
Stem below cut	0.2
Sixth leaf	55

A similar **work with the data** exercise may be assigned in **LaunchPad**.

In cold parts of the world, each year, deciduous trees lose their leaves and have bare branches and twigs over the winter (**Figure 33.17**). The apical meristems of the twigs are enclosed in buds protected by bud scales. When the buds begin to grow in spring, the scales fall away, leaving scars that show where the bud was. These scars allow us to identify the parts of the twig from each year's growth. The dormant twig shown in **Figure 33.17** is the product of both primary and secondary growth. The buds consist entirely of primary tissues.

Figure 33.17 A Woody Twig Has Both Primary and Secondary Growth The apical meristems in this dormant twig will produce primary growth in spring. Lateral meristems are responsible for secondary growth.

The vascular cambium is initially a single layer of cells lying between the primary xylem and the primary phloem within the vascular bundles. The root or stem increases in diameter when

the cells of the vascular cambium divide, producing secondary xylem cells toward the inside of the root or stem and producing secondary phloem cells toward the outside. In the stem, cells in the pith rays between the vascular bundles also divide, forming a continuous cylinder of vascular cambium running the length of the stem. This cylinder, in turn, gives rise to complete cylinders of secondary xylem (the **wood**) and secondary phloem, which contributes to the bark. It also produces vascular rays for lateral transport, a structure not found in primary xylem and phloem. Therefore the vascular cambium produces vessel elements, tracheids, parenchyma cells, and supportive fibers in the secondary xylem; and sieve tube elements, companion cells, fibers, and parenchyma cells in the secondary phloem.

wood Secondary xylem tissue.

Animation 33.1 **Secondary Growth: The Vascular Cambium** www.Life11e.com/a33.1

As secondary growth of stems or roots continues, the expanding vascular tissue stretches and breaks the epidermis and the outer layers of the cortex, which ultimately flake away. Before these dermal tissues are broken away, cells lying near the surface of the secondary phloem begin to divide, forming a cork cambium. This meristematic tissue produces layers of cork, a protective tissue composed of cells with thick walls waterproofed with suberin. The cork soon becomes the outermost tissue of the stem or root (see [Figure 33.17](#)). Without the activity of the cork cambium, the sloughing off of the outer primary tissues would expose the plant to potential damage, such as excessive water loss or invasion by microorganisms. Sometimes the cork cambium produces cells toward the inside as well as the outside; these cells constitute a tissue known as the phelloderm.

The cork cambium, cork, and phelloderm constitute the secondary dermal tissue called periderm. As the vascular cambium continues to produce secondary vascular tissue, these corky layers are lost, but the continuous formation of new cork cambia in the underlying secondary phloem gives rise to new corky layers. The periderm and the secondary phloem—that is, all the tissues external to the vascular cambium—constitute the **bark**.

bark All tissues external to the vascular cambium of a plant.

When periderm forms on stems or roots, the underlying tissues still need to release carbon dioxide and take up oxygen for cellular respiration. Spongy regions in the periderm called **lenticels** can allow such gas exchange ([Figure 33.18](#)).

lenticels Small porous regions on the bark of woody stems and roots in dicots.

Figure 33.18 Lenticels Allow Gas Exchange through the Periderm The region of periderm that appears to be broken open is a lenticel in a year-old elderberry (*Sambucus*) twig; note the spongy tissue that constitutes the lenticel.

You may be curious about cork, which is used as stoppers in bottles of wine and in flasks in the chemistry lab. Cork is harvested from a tree, the cork oak (*Quercus suber*, see photo next page), which is grown for that purpose mainly in Portugal. The tree lives more than 100 years, and cork is first harvested when the tree is 25 years old. The outer bark is removed first, carefully exposing the cork layers, which are then removed without damaging the living tissues. The cork cambium then produces more cork, so a tree can be harvested every 10 years.

Cross sections of most tree trunks (stems) in temperate-zone forests show annual rings of wood ([Figure 33.19](#)), which result from seasonal environmental conditions. In spring, when water is relatively plentiful, the tracheids or vessel elements produced by the vascular cambium tend to be large in diameter and relatively thin-walled. Such wood is well adapted for transporting water and minerals. As water becomes less available during the summer, narrower cells with thicker walls are produced, making this summer wood darker and perhaps more dense than the wood formed in spring. Thus each growing season is usually recorded in a tree trunk by a clearly visible annual ring. Trees in the moist tropics do not undergo seasonal growth, so they do not lay down such obvious regular rings. Variations in temperature or water supply can lead

to the formation of more than one ring in a single year, but most commonly a single annual ring is formed. Next time you are in the woods and see a fallen tree, try to count the annual rings to gauge the age of a tree.

Figure 33.19 Annual Rings Rings of secondary xylem are the most noticeable feature of this cross section from a tree trunk.

Only eudicots and other non-monocot angiosperms, along with many gymnosperms, have a vascular cambium and a cork cambium and thus undergo secondary growth. The few monocots that form thickened stems—palms, for example—do so without secondary growth. Palms have a very wide apical meristem that produces a wide stem, and dead leaf bases add to the diameter of the stem. All monocots grow in essentially this way, as do other angiosperms that lack secondary growth.

33.3 recap

Meristems are localized regions of cell division that are the sources of all new organs in the adult plant. Apical meristems are responsible for primary growth, which is associated with the lengthening and branching of shoots and roots. Lateral meristems increase plant thickness and form wood and bark in many eudicots.

learning outcomes

You should be able to:

- Describe characteristics of determinate and indeterminate growth in plants.
- Compare meristematic with non-meristematic cells, and explain the function of meristematic cells in plant
- Analyze how apical meristems are able to produce different organs, including leaves,

stems, flowers, and roots.

- Describe or illustrate a longitudinal section of the developing root, and explain the functions of special zones of cells from the tip upward.
 - Explain how different types of meristem result in the various layers of the mature root.
-

1. How can an apical meristem be maintained for years while continuing to form leaves?
 2. Define the primary meristems of the plant and how tissues and organs are formed from them.
 3. What cells are derived from the root apical meristem, and what is the general process of root growth?
 4. Compare primary and secondary growth in a tree trunk in terms of the meristems involved, the tissues formed, and the result.
-

The building of the plant body by meristems allows a plant to respond to its environment by redirecting its growth. Thus individual plants of the same species can vary greatly in form. What underlies this variation, and how have we humans used it to our advantage?

***connect the concepts** The leaf is elegantly structured for the reactions of photosynthesis. For more detail on photosynthesis and the role of leaf tissues, see [Key Concepts 10.1](#) and [10.4](#).

33.4 Domestication Has Altered Plant Form

You have seen in this chapter that a simple, modular plant body plan underlies the remarkable diversity of the flowering plants that cover our planet. Differences in plant form among species are not surprising, given the high levels of genetic diversity among plant species. However, members of the same species can also show remarkable diversity in form. From a genetic perspective, this suggests that minor differences in gene content or gene regulation can underlie dramatic differences in plant form.

focus your learning

Genetic variation in the structure of plants is a valuable natural resource for crop plant evolution.

It is hard to believe that modern corn was domesticated from the wild grass teosinte, which still grows in the hills of Mexico ([Figure 33.20](#)). One of the most conspicuous differences is that teosinte, like other wild grasses, is highly branched, whereas domesticated corn has a single shoot. This morphological difference is due in large part to the activity of a single gene called *teosinte branched 1* (*tb1*). The protein product of *tb1* regulates the growth of axillary buds (see [Figure 33.1](#)). The allele of *tb1* in domesticated corn represses branching, whereas the allele in teosinte permits branching.

Figure 33.20 Modern Corn Was Domesticated from the Wild Grass Teosinte

Each teosinte plant has multiple branches. Beginning more than 8,000 years ago in Mexico, farmers favored plants with minimal branching. Reducing the number of branches results in fewer ears per plant but allows each ear to grow larger and produce more seeds.

Even harder to believe is that a single species, **Brassica oleracea* (wild mustard), is the ancestor of many familiar and morphologically diverse crops, including kale, broccoli, Brussels sprouts, and cabbage.

Each of these familiar vegetable crops has the same basic body plan. Starting with morphologically diverse populations of the wild ancestor, humans selected and planted the seeds of variants with traits they found desirable. For example, Brussels sprout plants were selected for their enlarged axillary buds, cabbage plants were selected for their enlarged terminal buds and short internodes, and broccoli and cauliflower plants were selected for their large clusters of flower buds. Many generations of such artificial selection produced the crops that fill the produce section of the supermarket and the stands of farmers' markets.

Just as they were for ancient farmers, the genomes of plants are priceless resources today. The genetic variation in crop plants and their wild relatives can be used to improve our crop plants or adapt them to changing conditions. The improvement of crop plants is a work in progress that is being carried out in plant breeding programs worldwide. These programs are now more important than ever. Increased human activity is dramatically changing our planet and leading to the extinction of more and more plant species. For this reason, various organizations around the world have developed seed banks, where seeds of diverse species, and variants within species, are stored.

33.4 recap

Crop domestication involves artificial selection of certain desirable traits found in wild plant populations. By understanding the basic body plan of plants, one can more easily understand the morphological relationship between a crop plant and its wild relatives.

learning outcomes

You should be able to:

- Discuss reasons why wild plant genomes should be preserved.

1. Why are the seeds from wild relatives of crop plants valuable?

investigatinglife

QA How might plant biologists improve the cassava plant for human use?

Many people depend on cassava roots for food. Unfortunately, the roots must undergo processing to remove sources of toxic cyanide before they are eaten. As you saw in Investigating Life: Understanding the Synthesis and Transport of Cyanogenic Glycosides, cyanide-forming molecules are formed in leaves and then transported to the roots through the vascular system. Molecular biologists have described the details of organ-specific synthesis of the machinery responsible for a major cyanogenic molecule. RNA interference (see [Key Concept 18.4](#)) has been used to block cassava leaves from making the toxic precursor, and as a result its concentration in the edible roots goes down by 99 percent compared with untreated plants. This is a promising way to reduce the requirements for processing of the crop.

Future directions

An international group of plant biologists and agricultural scientists has been set up to stimulate research on cassava. The BioCassava Plus Consortium has not only found ways to improve the nutritional quality of cassava, but has also sought ways to improve the plant's ability to grow in drought conditions. Cassava has been crossed with a treelike relative, *Manihot glaziovii*, and the resulting plants produce roots that are not only fleshy and edible but that grow deep into the soil, where they can tap into water supplies far below the surface in dry climates. The hope is that this new crop variant will improve conditions for people in drought-prone places such as sub-Saharan Africa, where tens of millions of people routinely experience famine.

Chapter Summary 33

33.1 The Plant Body Is Organized in a Distinctive Way

- The vegetative organs of flowering plants are roots, which form a [root system](#), and stems, leaves, and flowers, which form a [shoot system](#). **Review** [Figure 33.1](#)

root system The organ system that anchors a plant in place, absorbs water and dissolved minerals, and may store products of photosynthesis from the shoot system.

shoot system In plants, the organ system consisting of the leaves, stem(s), and flowers.

- Plant development differs from animal development in that plants have apical meristems, cell walls, vacuoles, and totipotent cells.
- Plants have apical-basal and radial axes of symmetry. **Review Figure 33.4**

▶ 33.2 Plant Organs Are Made Up of Three Tissue Systems

- Three tissue systems, arranged concentrically, extend throughout the plant body: the vascular tissue, dermal tissue, and ground tissue systems. **Review Focus: Key Figure 33.6**
- The **dermal tissue system** protects the plant body surface. Dermal cells form the **epidermis** and, in woody plants, the **periderm**.

dermal tissue system The system of cells that forms the outer covering of a plant, consisting of epidermis in the young plant and periderm in a plant with extensive secondary growth. (Contrast with ground tissue system, vascular tissue system.)

epidermis [Gk. *epi*: over + *derma*: skin] In plants and animals, the outermost cell layers. (Only one cell layer thick in plants.)

periderm The outer tissue of the secondary plant body, consisting primarily of cork.

- The **ground tissue system** contains cells of three types. Some **parenchyma** cells carry out photosynthesis; others store starch. **Collenchyma** cells provide flexible support. Sclerenchyma cells include **fibers** and **sclereids**, which provide strength and mechanical support. **Review Figure 33.7**

ground tissue system Those parts of the plant body not included in the dermal or vascular tissue systems. Ground tissues function in storage, photosynthesis, and support.

parenchyma (pair eng' kyma) A plant tissue composed of relatively unspecialized cells without secondary walls. (Contrast with collenchyma, sclerenchyma.)

collenchyma (cull eng' kyma) [Gk. *kolla*: glue + *enchyma*: infusion] A type of plant cell, living at functional maturity, which lends flexible support by virtue of primary cell walls thickened at the corners. (Contrast with parenchyma, sclerenchyma.)

fiber In angiosperms, an elongated, tapering sclerenchyma cell, usually with a thick cell wall, that serves a support function in xylem. (See also muscle fiber.)

sclereid One of the principle types of cells in sclerenchyma.

- The **vascular tissue system** includes **xylem**, which conducts water and minerals absorbed by the roots, and **phloem**, which conducts the products of photosynthesis throughout the plant body.

vascular tissue system The transport system of a vascular plant, consisting primarily of xylem and phloem. (Contrast with dermal tissue system, ground tissue system.)

xylem (zy' lum) [Gk. *xylon*: wood] In vascular plants, the tissue that conducts water and minerals; xylem consists, in various plants, of tracheids, vessel elements, fibers, and other highly

specialized cells.

phloem (flo' um) [Gk. *phloos*: bark] In vascular plants, the vascular tissue that transports sugars and other solutes from sources to sinks.

- **Tracheary elements** include **tracheids** and **vessel elements**, which are the conducting cells of the xylem. **Sieve tube elements** are the conducting cells of the phloem. **Review Figure 33.8**

tracheary element Either of two types of xylem cells—tracheids and vessel elements—that undergo apoptosis before assuming their transport function.

tracheid (tray' kee id) A type of tracheary element found in the xylem of nearly all vascular plants, characterized by tapering ends and walls that are pitted but not perforated. (Contrast with vessel element.)

sieve tube element The characteristic cell of the phloem in angiosperms, which contains cytoplasm but relatively few organelles, and whose end walls (**sieve plates**) contain pores that form connections with neighboring cells.

▶ 33.3 Meristems Build a Continuously Growing Plant

- All seed plants possess a primary plant body consisting of non-woody tissues. Woody plants also possess a secondary plant body consisting of wood and bark. **Apical meristems** generate the primary plant body, and **lateral meristems** generate the secondary plant body. **Review Figure 33.9**

apical meristem The meristem at the tip of a shoot or root; responsible for a plant's primary growth.

lateral meristem Either of the two meristems, the vascular cambium and the cork cambium, that give rise to a plant's secondary growth.

- Apical meristems are responsible for **primary growth** (lengthening of roots and shoots). Apical meristems at the tips of shoots and roots give rise to three **primary meristems** (**protoderm**, **ground meristem**, and **procambium**), which in turn produce the three tissue systems of the primary plant body.

primary growth In plants, growth that is characterized by the lengthening of roots and shoots and by the proliferation of new roots and shoots through branching. (Contrast with secondary growth.)

primary meristem Meristem that produces the tissues of the primary plant body.

procambium Primary meristem that produces the vascular tissue.

- The root apical meristem gives rise to the **root cap** and to three primary meristems. Root tips have overlapping **zones of cell division**, **cell elongation**, and cell maturation. **Review Figure 33.10**

root cap A thimble-shaped mass of cells, produced by the root apical meristem, that protects the meristem; the organ that perceives the gravitational stimulus in root gravitropism.

- The vascular tissue of roots is contained within the [stele](#). It is arranged differently in eudicot and monocot roots. **Review** [Figures 33.11](#), [Figures 33.12](#), [Activities 33.1](#), [33.2](#)

stele (steel) [Gk. pillar] The central cylinder of vascular tissue in a plant stem.

- In nonwoody stems, the vascular tissue is divided into [vascular bundles](#), each containing both xylem and phloem. **Review** [Figure 33.14](#), [Activities 33.3](#), [33.4](#)

vascular bundle In vascular plants, a strand of vascular tissue, including xylem and phloem as well as thick-walled fibers.

- Eudicot leaves have two zones of photosynthetic [mesophyll](#) that are supplied by veins with water and minerals. Veins also carry the products of photosynthesis to other parts of the plant body. A waxy [cuticle](#) limits water loss from the leaf. Guard cells control openings called **stomata** in the leaf that allow CO₂ to enter, but also allow some water to escape. **Review** [Figure 33.16](#), [Activity 33.5](#)

mesophyll (mez' uh fill) [Gk. *mesos*: middle + *phyllon*: leaf] Chloroplast-containing, photosynthetic cells in the interior of leaves.

cuticle (1) In plants, a waxy layer on the outer body surface that retards water loss. (2) In ecdysozoans, an outer body covering that provides protection and support and is periodically molted.

- Two lateral meristems, the [vascular cambium](#) and [cork cambium](#), are responsible for secondary growth. The vascular cambium produces secondary xylem (**wood**) and secondary phloem. The cork cambium produces a protective tissue called cork. **Review** [Figure 33.17](#), [Animation 33.1](#)

vascular cambium (kam' bee um) [L. *cambiare*: to exchange] In plants, a lateral meristem that gives rise to secondary xylem and phloem.

cork cambium [L. *cambiare*: to exchange] In plants, a lateral meristem that produces secondary growth, mainly in the form of waxy-walled protective cells, including some of the cells that become bark.

▶ 33.4 Domestication Has Altered Plant Form

- The plant body plan is simple, yet it can be changed dramatically by minor differences in genes, as evidenced by the natural diversity of wild plants.
- Crop domestication involves artificial selection of certain desirable traits found in wild populations. **Review** [Figure 33.20](#)

Review

- 3.3** Growth in plants can be either determinate or indeterminate, depending on the organ structure.
- 3.3** At the root meristem, zones of cell division, elongation, and maturation (differentiation) form the tissues of the root and root cap.
- 3.3** The root consists of several tissue layers outside of the inner vascular tissues. These tissues have different arrangements in eudicot and monocot roots.
- 3.3** Growth in terms of cell numbers occurs at meristems.

Original Paper: Doerner, P. 1998. Root development: Quiescent center not so mute after all. *Current Biology* 8: R42-R44.

Angiosperm root tissues are arranged in a cylinder with layers oriented from outside to inside and with a vascular cylinder composed of xylem and phloem in the center, as shown in [Figure A](#).

These tissue layers originate in root apical meristems from a small, rapidly dividing group of cells called "initials," located just above the root cap. Like stem cells in animals, initials are generalized and can differentiate into all types of plant tissues. The small group of initials surrounds a smaller group (usually four to eight cells) called the quiescent center (QC), where cells divide very slowly, as shown in [Figure B](#). For example, in corn (*Zea mays*), QC cells divide every 170 hours, while those in the zone of cell division divide every 10-16 hours.

To identify actively dividing cells, scientists incubate plant roots in radioactive thymidine, which enters and labels the DNA. Labeled cells are detected by a photographic technique. The table below shows simulated data for corn seeds incubated in radioactive thymidine for two hours and then removed to water containing non-radioactive thymidine. Numbers represent the number of labeled cells in various zones at different times. Results are shown in the table.

Number of hours after transfer to nonradioactive thymidine	Radioactive cells/total cells			
	Quiescent center	Initials (zone of division)	Zone of elongation	Zone of maturation
0	1/4	75/95	0/30	0/19
12	1/4	85/90	12/32	0/23
36	1/4	55/110	15/31	11/21
72	1/4	3/98	3/29	28/30
144	1/4	0/108	0/30	29/31
192	1/4	0/100	0/27	30/31

Figure A

Figure B

Questions

1. Why does the number of labeled cells in the zones of division and elongation decrease over time?
2. Based on the distribution of labeled cells in the table, what can be inferred about the direction and pattern of root growth in this plant?
3. Plant cells, unlike animal cells, do not migrate during embryogenesis. Given this situation, how might the small group of initials just above the root cap result in separate layers of root tissue arranged in a cylinder?
1. Researchers have suggested that the QC serves as a "stem cell reservoir" that replenishes initials and ensures the continued existence of the root apical meristem. Does the pattern of labeling in the QC over time support this hypothesis? Explain your answer.

***connect the concepts** The diversity of plants derived from wild mustard illustrated in [Figure 20.5](#) demonstrates how artificial selection the purposeful selection of specific phenotypes by humans can produce rapid evolutionary change.

34

Transport in Plants

Cultivation of rice, the most important food crop in Asia, requires large quantities of water.

key concepts

- [1.1 Plants Acquire Water and Minerals from the Soil](#)
- [1.2 Water and Minerals Are Transported in the Xylem](#)
- [1.3 Stomata Control the Loss of Water and the Uptake of CO₂](#)
- [1.4 Solutes Are Transported in the Phloem](#)

Thirsty Rice

Plants need a lot of water to grow. Crop plant cultivation consumes far more water than all other human activities combined. Meeting the demand is especially challenging in drought-prone regions, compelling us to understand how plants use water so that we can select or breed plants that use it more efficiently. Much of the mass that plants acquire as they grow is due to their net fixation of atmospheric CO_2 into carbohydrates through photosynthesis. The ratio of net photosynthetic carbon fixation into plant material to water uptake is known as a plant's water-use efficiency.

One of the least water-efficient of all crop plants is, unfortunately, one of our most important: rice. Rice plants use up to three times more water per unit of growth than crops such as wheat and corn. The precariousness of heavily water-dependent rice farming was dramatically demonstrated in eastern India between 1997 and 2003, when drought reduced rice production by more than 5 million tons—some farmers lost up to 50 percent of their crops.

A strain of rice requiring less water yet producing the same amount of grain would both make the world supply of rice less vulnerable to drought and help conserve water for other uses. A team of scientists began the quest for such a strain by studying the model organism *Arabidopsis thaliana*. They searched for mutations of *Arabidopsis* that had superior water-use efficiency. One genetic variant they studied has an extensive root system (indicating higher capacity for water uptake) and thick leaves with abundant photosynthetic tissue (indicating prolific photosynthesis). Molecular and physiological characterization linked the improved water usage of this *Arabidopsis* strain to a mutation in a single gene that codes for a transcription factor that the scientists called HARDY. This protein turns out to be a member of a family of transcription factors that plants use to regulate genes in response to biotic and abiotic stress. When biotechnologists isolated this gene (*HARDY*) and put it into rice plants, the transformed rice plants not only had higher water-use efficiency than wild-type rice plants but were more tolerant of dry soil as well.

Laboratories around the world are using *Arabidopsis* to isolate genes involved in water usage and other important physiological processes. The knowledge gained from these studies may lead to various improvements of crop plants.

What methods are used to reduce water loss in agriculture?

34.1 Plants Acquire Water and Minerals from the Soil

Terrestrial plants must obtain both water and mineral nutrients from the soil, through their roots, and the water is transported through the plant in xylem tissue. Carbohydrates and other important materials mostly originate in leaves and circulate through the phloem ([Figure 34.1](#)). Water is required for photosynthesis in the leaves (see [Key Concept 10.1](#)), for transporting solutes between plant organs, for cooling the plant, and for developing the internal pressure that supports the plant body.

Figure 34.1 The Pathways of Water and Solutes in a Plant Water travels from the soil to the atmosphere, with only a small fraction used within the plant.

focus your learning

Water potential is determined by solute potential and pressure potential.

Membrane proteins form channels (aquaporins, ion channels) and act as pumps that help move materials across cell membranes.

The two main pathways to get water from the soil into the xylem are the apoplast and the symplast.

Movement of water and ions across a cell membrane can be impeded.

The Casparian strip prevents water and ions in the apoplast from crossing the endodermis; to reach the xylem, they must enter the symplast.

The minerals that a plant needs are transported along with the water. Several steps in water and mineral transport will be considered in this chapter. In this section we will focus on the first part of the journey—the uptake of water and minerals into the roots and their transport into the xylem.

Water potential differences govern the direction of water movement

Water moves into and out of plant cells. The direction of water movement is determined by **water potential (Ψ , psi)**, defined as the tendency of water molecules to move in response to forces such as pressure or solute concentration gradients. In the case of plant roots in soil water, whenever water moves across a selectively permeable membrane by ***osmosis**, it moves toward the region of lower (more negative) water potential (**Figure 34.2A, left**). We measure water potential in megapascals (MPa), a unit of pressure. Atmospheric pressure, 1 atmosphere, is about 0.1 MPa, or 14.7 pounds per square inch; a typical pressure in an automobile tire is about 0.2 MPa.

water potential (Ψ , psi) In osmosis, the tendency for a system (a cell or solution) to take up water from pure water through a differentially permeable membrane.

(A) A theoretical illustration of water potential

(B) The effect of differences in water potential on a plant cell

Figure 34.2 Water Potential, Solute Potential, and Pressure Potential

Activity 34.1 Water Uptake in Plants www.Life11e.com/ac34.1

Water potential has two major components:

- **Solute potential (Ψ_s):** As solutes are added to pure water, the concentration of free water is reduced, the tendency to take up water increases, and water potential decreases.

solute potential (Ψ_s) A property of any solution, resulting from its solute contents; it may be zero or have a negative value. The more negative the solute potential, the greater the tendency of the solution to take up water through a differentially permeable membrane. (Contrast with pressure potential, water potential.)

- **Pressure potential (Ψ_p):** As plant cells take up water, they tend to swell. However, the presence of the cell wall provides resistance to swelling (see [Figure 6.10](#)). The result is an increase in pressure inside the cell (**turgor pressure**), which decreases the tendency of the cell to take up more water (increases the water potential) ([Figure 34.2A, right](#)).

pressure potential (Ψ_p) The hydrostatic pressure of an enclosed solution in excess of the surrounding atmospheric pressure. (Contrast with solute potential, water potential.)

A solution's water potential is the sum of its (usually negative) solute potential (Ψ_s) and its (usually positive) pressure potential (Ψ_p):

$$\Psi = \Psi_s + \Psi_p \quad \Psi = \Psi_s + \Psi_p$$

By definition, the solute potential of pure water is zero (no solutes); because added solutes decrease water potential, solute potential is usually negative. Pressure potential is defined as zero when it equals atmospheric pressure. Pressure potential less than atmospheric pressure is negative; pressure potential greater than atmospheric pressure is positive.

In a plant cell immersed in pure water ([Figure 34.2B](#)), turgor pressure is comparable to the pressure potential exerted by the piston in [Figure 34.2A](#). Water enters the cell by osmosis until the pressure potential exactly balances the solute potential and the water potential is zero. At this point the cell is **turgid**—that is, it has a significantly positive pressure potential. Plant cells are surrounded by water with dissolved solutes rather than pure water, and their water potential is dependent on the water potential in the soil. But because turgid cells have a positive pressure potential, there is no net movement of water into them. The physical structures of many plants are maintained by the positive pressure potential of the water in their cells. If the pressure potential drops (for example, if the plant does not have enough water), the plant wilts ([Figure 34.3](#)).

turgid Swollen or distended. In plants, a cell is turgid when its water potential is lower than that of the surrounding environment.

Figure 34.3 A Wilting Plant A plant wilts when the pressure potential in its cells (the turgor pressure) is low.

Q: Sometimes a plant will wilt even if it is adequately watered because of an excess of fertilizer (dissolved ions in the soil). Why?

In living plant tissues, the movement of water from cell to cell follows a gradient of water potential. But over longer distances, in unobstructed tubes such as xylem vessels, the flow of water and dissolved solutes is driven by a *gradient of pressure potential*, not a gradient of water potential. The movement of a solution from a region of higher pressure potential to a region of lower pressure potential is called **bulk flow**.

bulk flow The movement of a solution from a region of higher pressure potential to a region of lower pressure potential.

Water and ions move across the root cell's cell membrane

Now that you've seen how water can move into plant cells by osmosis, what about ions? And what is the role of the cell membrane? The movement of water and mineral ions across a root cell membrane can be impeded for two reasons:

- . The interior of the membrane is hydrophobic, whereas water and mineral ions are polar.
- . Some mineral ions must be moved against their concentration gradients.

However, as you saw in [Chapter 6](#), membrane proteins assist with the movement of materials across membranes:

Aquaporins. Aquaporins (see [Key Concept 6.3](#)) are located in both the cell membrane and the tonoplast (vacuolar membrane) of a plant cell. Aquaporins allow water to diffuse rapidly across these membranes. The number of aquaporins in a particular cell depends on that cell's need to obtain and retain water, and can vary with environmental conditions. The permeability of some aquaporins also can be regulated. Alterations in aquaporin abundance and permeability change the *rate* of osmosis across the membrane. Note that water movement through

aquaporins is always passive: from a region of higher water potential to one of lower water potential.

Ion channels and pumps. When the concentration of a charged ion in the soil is greater than that in the plant, transport proteins can move the ions into the plant by facilitated diffusion, which is a passive process (see [Key Concept 6.3](#)). The concentrations of most ions in the soil solution, however, are lower than those inside the plant. In these cases the plant must actively take up ions *against* their concentration gradients—a process that requires energy (see [Key Concept 6.4](#)).

Electric charge differences also play a role in the uptake of mineral ions. For example, a negatively charged ion that moves into a negatively charged compartment is moving against an *electrical gradient*, and this requires energy. Concentration and electrical gradients combine to form an ***electrochemical gradient**. Uptake against an electrochemical gradient involves active transport, which requires energy and specific transport proteins.

Unlike animals, plants do not have a sodium-potassium pump (described in [Key Concept 6.4](#)) to drive active transport. Rather, plants have a **proton pump**, which uses energy obtained from ATP to move protons out of the cell against a proton concentration gradient ([Figure 34.4, Step1](#)). Because protons (H^+) are positively charged, their accumulation outside the cell has two results:

proton pump An active transport system that uses ATP energy to move hydrogen ions across a membrane, generating an electric potential.
--

Figure 34.4 The Proton Pump in Transport of K^+ and Cl^- The active transport of hydrogen ions (H^+) out of the cell by the proton pump (1) drives the movement of both cations (2) and anions (3) into the cell.

- An electrical gradient is created, with the region outside the cell more positively charged than the inside.
- A proton concentration gradient develops, with more protons outside the cell than inside.

Both the electrical gradient and the concentration gradient assist with the movement of other ions into the cell. Because the inside of the cell is more negative than the outside, cations (positively charged ions) such as potassium (K^+) can move into the cell by facilitated diffusion through specific membrane channels ([Figure 34.4, Step 2](#)). In addition, the proton concentration gradient can be harnessed to drive secondary active transport, in which anions (negatively charged ions) such as chloride (Cl^-) are moved into the cell. These ions can move against the electrochemical gradient because symport proteins couple their movement with that of H^+ ([Figure 34.4, Step 3](#)).

Water and ions pass to the xylem by way of the apoplast and symplast

The journey from the soil through the roots to the xylem occurs primarily by one of two pathways, either separately or simultaneously: the fast lane (called the apoplast) and the

slow(er) lane (called the symplast) ([Figure 34.5](#)):

Figure 34.5 Apoplast and Symplast Plant cell walls and intercellular spaces constitute the apoplast. The symplast comprises the living cells connected by plasmodesmata. To enter the symplast, water and solutes must pass through a cell membrane. No such selective barrier limits movement through the apoplast.

Q: What type of animal cell junction is best compared with the Casparian strip? See [Figure 6.7](#).

- The **apoplast** (Greek *apo*, “away from”; *plast*, “living material”) consists of the cell walls, which lie outside the cell membranes, and the intercellular spaces (spaces between cells) that are common in many plant tissues. Typically, the apoplast occupies 5-20 percent of plant tissues by volume. The apoplast is a continuous meshwork through which water and dissolved substances can flow without ever having to cross a membrane. Movement of materials through the apoplast is thus unregulated and rapid.

apoplast (ap' oh plast) In plants, the continuous meshwork of cell walls and extracellular spaces through which material can pass without crossing a plasma membrane. (Contrast with symplast.)

- The **symplast** (Greek *sym*, “together with”) is the continuous cytoplasm of the living cells, which are connected by plasmodesmata (see [Figure 7.16B](#)). Secretory cells such as those in flowers that make nectar have a lot of plasmodesmata. So do cells in the root tip, where the selectively permeable cell membranes of the root cells control access to the symplast. Movement of water and dissolved substances into the symplast is tightly regulated.

symplast The continuous meshwork of the interiors of living cells in the plant body, resulting from the presence of plasmodesmata. (Contrast with apoplast.)

Water and minerals that pass from the soil solution through the apoplast can travel as far as the endodermis, the innermost layer of the root cortex ([Figure 34.6](#); see [Key Concept 33.3](#)). The endodermis is distinguished from the rest of the ground tissue by the presence of the **Casparian strip**. This waxy, suberin-impregnated region of the endodermal cell wall forms a hydrophobic belt around each endodermal cell where it is in contact with other endodermal cells. The Casparian strip acts as a seal that prevents water and ions from moving through apoplastic

spaces between the endodermal cells. Therefore all water and ions must enter the symplast in order to cross the endodermis into the stele, which contains the vascular tissues of the root. The materials pass from the endodermal cells to cells in the stele via plasmodesmata.

Casparian strip A band of cell wall containing suberin and lignin, found in the endodermis. Restricts the movement of water across the endodermis.

Figure 34.6 Pathways to the Root Xylem Water and solutes can move into the root through the symplast or the apoplast until they reach the endodermis (shown in dark green); there the water and solutes must enter the symplast to bypass the Casparian strip (purple), a region of the endodermal cell wall that is impregnated with the water-repelling substance suberin. Inside the stele, the water and solutes enter the xylem (blue).

Activity 34.2 Apoplast and Symplast of the Root www.Life11e.com/ac34.2

Once they have passed the endodermal barrier, water and minerals remain in the symplast until they reach parenchyma cells in the pericycle or xylem. These cells then actively export mineral ions into the apoplast of the stele. As the concentrations of mineral ions in the apoplast increase, its water potential becomes more negative. Consequently, water moves out of the cells and into the apoplast by osmosis. In other words, ions are transported actively, and water follows passively. The end result of transport is that water and minerals end up in the xylem, where they constitute the **xylem sap**. [Table 34.1](#) shows the composition of xylem sap.

xylem sap The liquid contents of the xylem.

table 34.1 Composition of Xylem and Phloem Fluids

Substance	Xylem	Phloem
Ions, minerals (g/L)	0.2-4	1-5
Amino acids (g/L)	0.1-1	5-40
Sugars (g/L)	0	100-300
Solute potential, ψ_s (MPa)	-0.02 to -0.2	-0.6 to -3

34.1 recap

Differences in water potential govern the osmotic flow of water from the soil into the plant stele; this is a passive process. Uptake of minerals from the soil that occurs along an electrochemical gradient is an active process requiring energy and membrane transport proteins. Water and minerals can move into the root vascular tissue through either the apoplast or the symplast, but must use the sym-plast pathway to reach the xylem.

learning outcomes

You should be able to:

- Describe or illustrate how solute potential and pressure potential affect the movement of water across the plant cell membrane.
- Describe how aquaporins, ion channels, and ion pumps affect the movement of water and solutes across the plant cell membrane.
- Discuss the roles of the apoplast and the symplast in moving water from the soil to the xylem.

1. What is the role of the cell wall in determining the direction of water movement and plant form?
2. A major component of root growth is osmotically driven cell expansion, which is achieved by the formation and swelling of the central vacuole. What role would you predict the expressions of aquaporins be in this cell expansion?
3. What are the differences between the apoplast and the symplast?

So far we've described the movement of water and minerals into plant roots and their entry into the root xylem. How does the xylem sap move once it is in the xylem?

***connect the concepts** The key to water movement is osmosis. You can review the process of osmosis and the role of the cell membrane in [Key Concept 6.3](#).

*** connect the concepts** Electrochemical gradients are important in many biological systems. Learn more about electrochemical gradients, and their role in the animal nervous system, in [Key Concept 44.2](#).

34.2 Water and Minerals Are Transported in the Xylem

Once water has arrived in the xylem, it is all "uphill" from there. Before considering the ascent of water and minerals to the leaves, reacquaint yourself with the cells that make up the xylem: the tracheids and vessel elements (see [Figure 33.8A](#) and B). Recall that these xylem cells are dead and lack all cell contents. When fused end-to-end, they form long tubular "straws" of lignified cell walls called [xylem vessels](#). These vessels provide both structural support and the rigidity needed to maintain a gradient of pressure.

xylem vessels Continuous tubes that conduct water in plants.

focus your learning

Xylem vessels must move large amounts of water upward for long distances.

Experiments ruled out two possible mechanisms for movement of water upward through the xylem.

The currently accepted mechanism for water transport through the xylem is the transpiration-cohesion-tension mechanism.

There is evidence to support all parts of the transpiration-cohesion-tension mechanism.

Consider the magnitude of what the xylem accomplishes. A single maple tree 15 meters tall was estimated to have some 177,000 leaves, with a total leaf surface area of 675 square meters—about one and a half times the area of a basketball court. During a summer day, that tree loses 220 liters of **water per hour* to the atmosphere by evaporation from the leaves. So to prevent wilting, the xylem needs to transport 220 liters of water up to 15 meters from the roots to the leaves every hour. (By comparison, a 50-gallon drum holds 189 liters.)

Various hypotheses have proposed how water moves in the xylem

Until the twentieth century, two mechanisms for moving water through the xylem were under consideration: upward pressure by living cells and capillary action. Both of these possibilities were largely ruled out by experiments:

A simple experiment in 1893 ruled out the hypothesis that root cells might initiate a *pumping mechanism* to propel water upward. A tree was cut at its base and the sawed-off part was placed in a vat containing a solution of poison that killed living cells. The poison rose up the trunk, killing any living cells it encountered along the way. The experiment demonstrated that a living pump in the root is not necessary to push the xylem sap up a tree. Because the roots were absent, it was clear that they are not involved in movement through the xylem.

Furthermore, when the poison sap reached the leaves, they died and all upward movement of the solution stopped, showing that living leaves are necessary for water to move in the xylem.

Because of its surface tension (see [Key Concept 2.4](#)) and adhesive forces between water and its container, water will move up a narrow column by a mechanism called *capillary action*.

You've seen this when you put a straw into a cup of water. Capillary action was ruled out as a

primary mechanism for upward xylem sap transport when calculations showed that xylem vessels (at 100 micrometers [μm] in diameter) are too wide to get water to the top of a 15-meter tree in this fashion. In fact, the maximum height for a water column raised by capillary action alone in a 100 μm tube would be only 0.15 meters.

The transpiration-cohesion-tension mechanism accounts for xylem transport

The current model of xylem transport involves three processes (**Focus: Key Figure 34.7**):

- . *Transpiration* of water molecules from the leaves by evaporation
- . *Tension* (negative pressure) in the xylem sap resulting from transpiration from the leaves
- . *Cohesion* of water molecules in the xylem sap, from the leaves to the roots

focus: key figure

Figure 34.7 The Transpiration-Cohesion-Tension Mechanism Transpiration causes evaporation from mesophyll cell walls, generating tension on the xylem. Cohesion among water molecules in the xylem transmits the tension from the leaf to the root, causing water to flow in the xylem from the roots to the atmosphere.

Q: What would be the effect of high relative humidity in the air around the leaves on root uptake of water? Explain.

Media Clip 34.1 **Inside the Xylem** www.Life11e.com/mc34.1

Animation 34.1 **Xylem Transport** www.Life11e.com/a34.1

The concentration of water vapor in the atmosphere is lower than that in the air spaces inside the leaf. Because of this difference, water vapor diffuses from the intercellular spaces of the leaf to the outside air, in a process called **transpiration**. Within the leaf, water evaporates from the moist walls of the mesophyll cells and enters the intercellular spaces. As water evaporates from the aqueous film coating each cell, the film shrinks back into tiny spaces in the cell walls, increasing the curvature of the water surface and thus increasing its surface tension. This increased *tension* (negative pressure potential) in the surface film draws more water into the walls from the cells, replacing that which was lost. The resulting tension in the mesophyll draws water from the xylem of the nearest vein into the apoplast surrounding the mesophyll cells. The removal of water from the veins, in turn, establishes tension on the entire column of water contained in the xylem. *Cohesion* between water molecules in the column prevents the column from breaking. So these three forces—transpiration, tension, and cohesion—operate together to draw water up the xylem, all the way from the roots to the leaves.

transpiration [L. *spirare*: to breathe] The evaporation of water from plant leaves and stem, driven by heat from the sun, and providing the motive force to raise water (plus mineral nutrients) from the roots.

Each part of this theory is supported by evidence:

The difference in water potential between the soil solution and the air is huge, on the order of 100 MPa. This difference should generate more than enough tension to pull a water column up a tree.

There is a continuous column of water in the xylem, which is made possible by the cohesive forces holding water molecules together.

Actual measurements of xylem pressures in cut stems show negative pressure potentials, indicating considerable tension in the xylem.

The transpiration-cohesion-tension mechanism accounts for the movement of water through the xylem. Dissolved mineral ions are carried along with the water to all of the plant's living tissues, where the ions are used for various cellular processes (see **Chapter 35** for more on plant nutrition). In addition to promoting the transport of minerals, transpiration has an added benefit of cooling a plant's leaves. The evaporation of water from mesophyll cells consumes heat, thereby decreasing the leaf temperature. A farmer can hold a leaf between thumb and forefinger to estimate its temperature; if the leaf doesn't feel cool, that means transpiration is not occurring and it must be time to water.

As you saw in the opening investigation of this chapter, farmers strive to improve the water-

use efficiency of their crops. The roles of the root system and transpiration are important. A gene from the model plant *Arabidopsis* has been shown to improve water-use efficiency by encoding a transcription factor that regulates genes involved in these processes ([Investigating Life: Improving Water-Use Efficiency in Rice](#)).

investigatinglife Improving Water-Use Efficiency in Rice

experiment

Original Paper: Karaba, A. et al. 2007. Improvement of water use efficiency in rice by expression of *HARDY*, an *Arabidopsis* drought and salt resistance gene. *Proceedings of the National Academy of Sciences USA* 104: 15270–15275.

The objective of improving rice production involves cultivating a large amount of plant material (biomass)—meaning a large amount of grain—while using less water. The relationship between biomass produced and water consumed is called water-use efficiency. A team at Virginia Polytechnic University led by Andrew Pereira approached this problem by isolating a gene that confers drought resistance from the model plant *Arabidopsis*. This gene, called *HARDY*, encodes a transcription factor in the AP/ERF family that activates transcription of genes involved in the plant's response to stresses. The team showed that *Arabidopsis* strains that expressed the *HARDY* transcription factor were much more resistant to drought and to an environment high in dissolved salts. They then inserted the *HARDY* gene into a high-expressing vector and made transgenic rice plants. Initial studies showed that the plants were drought-resistant.

HYPOTHESIS ▶ A gene from *Arabidopsis* confers drought resistance and improves water-use efficiency.

CONCLUSION ▶ High expression of the *Arabidopsis* gene *HARDY* in rice plants confers drought resistance and improved water-use efficiency.

work with the data

The investigators measured a number of parameters in both wild-type and transgenic *HARDY* rice:

- Water-use efficiency: g carbon fixed/kg water used
- Transpiration rate: water lost in g/cm² plant area/day
- Carbon fixation rate: g/cm² plant area/day
- Biomass accumulation: g in root + shoot

Results are shown in the table and expressed as mean ± SD.

Parameter	Wild-type	<i>HARDY</i>
Water-use efficiency	1.5 ± 0.06	3.0 ± 0.5
Transpiration rate	5.2 ± 0.2	4.0 ± 0.4
Carbon fixation rate	0.7 ± 0.06	1.3 ± 0.06
Biomass accumulation	7.5 ± 0.5	13.0 ± 0.6

QUESTIONS

1. Explain each result.
2. What statistical test would you use to evaluate the significance of any differences found?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

METHOD

- 1 Isolate from *Arabidopsis* DNA sequences associated with the transcription and translation of the *HARDY* gene.

- 2 Link *HARDY* to active promoter in an expression vector.

- 3 Transform rice plant seedlings.

- 4a Water to 100% soil saturation (control),

- 4b Water to 70% soil saturation (drought),

- 5 Observe plant phenotype and measure water-use efficiency.

RESULTS

The transpiration-cohesion-tension mechanism explains the ascent of xylem sap. Transpiration draws water out of leaves, resulting in tension that pulls water from the xylem. Because of cohesion between water molecules, water is pulled passively through the xylem vessels in continuous columns, always toward a region with lower pressure potential.

learning outcomes

You should be able to:

- Solve problems relating to the transport of water by the xylem when given information on water potential.
- Describe how scientists ruled out past hypotheses for upward flow of water in plants.
- Discuss the interaction of the processes of transpiration, cohesion, and tension in the movement of water upward through the xylem.
- Provide evidence for the importance of each of the processes of transpiration, cohesion, and tension in the movement of water through the xylem.

1. What experiment ruled out the role of pressure from the roots in the upward flow of water in the xylem?
2. The table at right shows measurements of water potential (Ψ) in a 100-meter-tall tree and its surroundings:

Region	Ψ (Mpa)
Soil water	-0.3
Xylem of root	-0.6
Xylem of trunk	-1.2
Inside of leaf	-2.0
Outside air	-58.5

Gravity exerts a force of -0.01 MPa per meter of height above ground.

- a. Is the water potential in the leaf sufficiently low to draw water to the top of the tree?
 - b. Would transpiration continue if soil water potential decreased to -1.0 MPa?
 - c. What would you expect to happen to the xylem water potential if all of the stomata closed?
3. Explain why all three parts of the transpiration-cohesion-tension mechanism are necessary for water transfer through the xylem.
 4. What types of evidence provide support for the transpiration-cohesion-tension mechanism of water transport through the xylem?

Although transpiration provides the driving force for the transport of water and minerals in the xylem, it also results in the loss of tremendous quantities of water from the plant. How plants control this loss will be the subject of the next section.

*** connect the concepts** As you learn about water movement in the xylem, keep in mind the properties of water described in [Key Concept 2.4](#).

34.3 Stomata Control the Loss of Water and the Uptake of CO₂

The epidermis of leaves and stems secretes a waxy cuticle, which is impermeable to water and thus helps minimize the loss of water from transpiration. However, the cuticle is also impermeable to carbon dioxide. The cuticle poses a dilemma: how can the plant balance its need to retain water with its need to obtain CO₂ for photosynthesis?

focus your learning

Stomata in leaves provide a balance between water loss and carbon dioxide diffusion into cells.

Environmental factors affect the opening and closing of stomata; numbers of stomata can also change if the plant sheds leaves or grows new leaves.

Stomata control water loss and gas exchange

An elegant compromise has evolved in plants in the form of pores called **stomata** (singular *stoma*) in the epidermis of their leaves. A pair of specialized epidermal cells, called **guard cells**, controls the opening and closing of each stoma ([Figure 34.8A](#)). When the stomata are open, CO₂ can enter the leaf by diffusion—but water vapor diffuses out of the leaf at the same time. Closed stomata prevent water loss but also exclude CO₂ from the leaf.

guard cells In plants, specialized, paired epidermal cells that surround and control the opening of a stoma (pore).

(A) An open stoma

(B) Ion concentration effects on stomatal opening

Figure 34.8 Stomata (A) Scanning electron micrograph of an open stoma formed by two sausage-shaped guard cells. (B) Potassium ion concentrations affect the water potential of the guard cells, controlling the opening and closing of stomata. Negatively charged ions (e.g., Cl^-) that accompany K^+ maintain electrical balance and contribute to the changes in water potential that open and close the stomata.

Most plants open their stomata only when the light intensity is sufficient to maintain a moderate rate of photosynthesis. At night, when darkness precludes photosynthesis, their stomata are closed; no CO_2 is needed, and water is conserved. Even during the day, the stomata close if water is being lost at too rapid a rate.

Stomata are ancient structures; they have been found in plant fossils that are more than 400 million years old. For this reason they are thought to predate the evolution of leaves. Stomata are found in all vascular plants and in many nonvascular plants, including mosses (but not liverworts; see [Chapter 27](#)).

The stoma and guard cells seen in [Figure 34.8A](#) are typical of eudicots. Monocots typically

have specialized epidermal cells associated with their guard cells. However, the principle of operation, which we will now describe in more detail, is the same for both monocot and eudicot stomata.

The guard cells control the size of the stomatal opening

The opening and closing of stomata are regulated by several environmental factors, including light, CO₂ levels, temperature, and water availability. Plants can also change the total number of stomata in response to longer-term changes in environmental conditions.

LIGHT AND CO₂ CONCENTRATION

Guard cells can respond to changes in light and CO₂ concentration in a matter of minutes by changing their solute potential. The absorption of light by a pigment in the guard cell's cell membrane activates a proton pump (see [Figure 34.4](#)), which actively transports H⁺ out of the guard cells and into the apoplast of the surrounding epidermis. The resulting electrochemical gradient drives K⁺ into the guard cells, where it accumulates ([Figure 34.8B](#)). Negatively charged chloride (Cl⁻) ions and organic ions also move into and out of the guard cells along with the K⁺ ions, maintaining electrical balance. The increased concentration of K⁺ and other solutes inside the guard cells makes the solute potential of the guard cells more negative. Water then enters by osmosis, increasing the turgor pressure of the guard cells. The guard cells change their shape, becoming more turgid in response to the increase in pressure potential, so that a space—the stoma—appears between them. The stoma closes in the absence of light: the proton pump becomes less active, K⁺ ions diffuse passively out of the guard cells, water follows by osmosis, the pressure potential decreases, and the guard cells sag together and seal off the stoma. Guard cell membranes are particularly rich in aquaporins, making guard cells well adapted for the rapid water movements involved in stomatal responses.

WATER

Stomata also respond to water availability. Water stress is a common problem for plants, especially on a hot, windy day, when plants might close their stomata even when the sun is shining. The water potential of the leaf's mesophyll cells is the cue for this response. If the mesophyll becomes dehydrated, its cells release the hormone abscisic acid, which causes the stomata to close.

STOMATA NUMBER

A plant can regulate water loss not just by the opening or closing of stomata, but by changing the number of stomata. The process of controlling the number of stomata takes place over days or weeks. Trees, for example, can reduce stomata numbers by shedding leaves, or by making new leaves that have few stomata.

34.3 recap

CO₂, which is needed for photosynthesis, enters leaves via tiny pores called stomata. Stomata also permit the loss of water by transpiration. Guard cells open or close stomata in response to a variety of environmental cues. Plants control their total numbers of stomata by shedding leaves or by altering the density of stomata on new leaves.

learning outcomes

You should be able to:

- Analyze reasons why stomata do not always remain open, considering the processes of

both photosynthesis and water conservation.

- Analyze the importance of the proton pump and K^+ ions in the actions of stomata, and list environmental changes that trigger the opening and closing of stomata.
-

1. What is the role of K^+ ions in the functioning of guard cells?

2. Describe how water availability can affect stomatal function.

Stomata are normally open during daylight hours, allowing photo-synthesis-the production of carbohydrates from CO_2 and water. In the next section we'll discuss how the products of photosynthesis are delivered to other parts of the plant, supporting plant growth.

34.4 Solutes Are Transported in the Phloem

Photosynthesis occurs primarily in the leaf (see [Figure 10.1](#)). The carbohydrate products of photosynthesis (mainly sucrose) diffuse to the nearest small vein (composed of xylem and phloem), where they are actively transported into sieve tube elements of the phloem. The movement of carbohydrates and other solutes through the phloem is called [translocation](#).

translocation (1) In genetics, a rare mutational event that moves a portion of a chromosome to a new location, generally on a nonhomologous chromosome. (2) In vascular plants, movement of solutes in the phloem.

focus your learning

Phloem sap is transported, or translocated, from sources to sinks in plants.

Translocation in plants is explained by the pressure flow model.

Two steps in translocation, loading and unloading, involve active transport, which requires energy.

The products of photosynthesis are called [photosynthates](#), and the content of the phloem is called the [phloem sap](#) (see [Table 34.1](#)). Translocation of phloem sap throughout the plant is by bulk flow, from sources to sinks:

photosynthates Carbohydrate products of photosynthesis.

phloem sap Liquid contents on the phloem tubes.

A [source](#) is an organ (such as a mature leaf or a storage root) that *produces*, by photosynthesis or by digestion of stored reserves, more sugars than it requires.

source In plants, any organ that exports the products of photosynthesis in excess of its own needs, such as a mature leaf or storage organ. (Contrast with sink.)

A [sink](#) is an organ (such as a root, flower, developing fruit, or immature leaf) that *consumes* sugars for its own growth and storage needs of the plant.

sink In plants, any organ that imports the products of photosynthesis, such as roots, developing fruits, and immature leaves. (Contrast with source.)

Sources and sinks can change roles. For example, the storage roots of cassava (see [Chapter 33](#)) are sinks when they accumulate carbohydrates but are sources when their stored carbohydrates are mobilized to nourish other organs when the plant grows.

Sucrose and other solutes are carried in the phloem

Evidence that the phloem carries sugar and other solutes was first obtained in the 1600s when the Italian scientist Marcello Malpighi removed a ring of bark from the trunk of a tree—that is, he “girdled” the tree. The bark contained the phloem, while the xylem in the underlying wood remained intact. Over time, the bark in the region above the girdle swelled:

Malpighi correctly concluded that a solution coming from the leaves above the girdle was trapped in the bark. Later the bark below the girdle died, presumably because it no longer received nutrients from the leaves. Eventually the roots, and then the entire tree, died—suggesting that sugar transport might occur in the phloem.

The cells that make up the phloem's conducting tubes are sieve tube elements (see [Figure 33.8C](#)). Like the vessel elements in the xylem, sieve tube elements meet end-to-end. However, unlike vessel elements, whose end walls are broken down as they mature, sieve tube elements retain their end walls. Communication between sieve tube elements is achieved by plasmodesmata in their end walls. During sieve tube development, the diameter of these plasmodesmata increases 10- to 100-fold, resulting in pores that allow the flow of phloem sap between neighboring cells. Because the end walls of sieve tube elements look and function like sieves, they are called **sieve plates** ([Figure 34.9](#)).

Figure 34.9 Sieve Tubes Individual sieve tube elements join together to form long tubes that transport carbohydrates and other nutrient molecules throughout the plant body in the phloem. Sieve plates form at the ends of each sieve tube element, and phloem sap passes through the pores in the sieve plate.

What happens next is truly remarkable and makes sieve tube elements among the most unusual cell types in nature. As the holes in the sieve plates expand, most of the cell contents are lost, including the nucleus, Golgi apparatus, and most of the ribosomes and cytoskeleton. Despite this, sieve tube elements live for an entire growing season in deciduous trees, and for decades in some other plants. How can sieve tube elements live for so long with no nucleus? The answer is that each sieve tube element has one or more [companion cells](#) (see [Figure 34.9](#)). Companion cells are produced as daughter cells along with the sieve tube elements when parent cells divide. Numerous plasmodesmata link a companion cell with its neighboring sieve tube element. Companion cells retain all their organelles and provide all the components needed to maintain the sieve tube elements—they may be thought of as the "life support systems" of the sieve tube elements.

companion cell In angiosperms, a specialized cell found adjacent to a sieve tube element.

Plant biologists have used aphids to precisely analyze the contents of the phloem. Aphids are insects that feed on plants by drilling into sieve tube elements with a specialized organ, the stylet. The pressure potential in the sieve tube is higher than that outside the plant, so the phloem contents are forced through the stylet into the aphid's digestive tract. So great is the pressure that some of the liquid is forced through the insect's body and out its anus.

If an aphid is frozen in the act of feeding, its body can be chopped off the plant stem, leaving the stylet intact. Phloem sap continues to flow from the stylet for hours, and can be collected for analysis. These and other experiments led to several important observations:

Sucrose makes up 90 percent of the phloem sap solutes. The phloem sap also contains hormones, proteins, small molecules such as amino acids, mineral nutrients, and viruses.

The flow rate can be very high, as much as 150 centimeters per hour.

Different sieve tube elements conduct their contents in different directions—for example, up or down the stem. Therefore the overall movement in the phloem is bidirectional.

The movement of phloem sap requires living cells, in contrast to movement in the xylem.

The pressure flow model accounts for translocation in the phloem

The observations we just described have led to the **pressure flow model** as an explanation for translocation in the phloem ([Figure 34.10](#)). According to this model, sucrose is actively transported at a source into companion cells, from which it flows through plasmodesmata into the sieve tube elements. This gives those cells a higher sucrose concentration than the surrounding cells (a more negative solute potential), and water therefore enters the sieve tube elements from the xylem by osmosis. The entry of this water increases turgor pressure (causes a more positive pressure potential) at the source end of the sieve tube, so that the entire fluid content of the sieve tube is pushed toward the sink end of the tube—in other words, the sap moves in response to a pressure gradient. In the sink, the sucrose is unloaded both passively and by active transport, and water moves back into the xylem. In this way, the gradient of solute potential and pressure potential needed for the movement of phloem sap (translocation) is maintained.

Figure 34.10 The Pressure Flow Model Water potential differences produce a pressure gradient and bulk flow of phloem sap from sources to sinks.

Animation 34.2 **The Pressure Flow Model** www.Life11e.com/a34.2

Two steps in phloem translocation require metabolic energy:

- Loading:** Transport of sucrose and other solutes from sources into companion cells and then into the sieve tubes.

loading In phloem, the process of transferring the products of photosynthesis, usually sugars, into sieve tubes.

- Unloading:** Transport of solutes from the sieve tubes into sinks. The need for ***metabolic energy** is the reason why phloem transport, unlike xylem transport, requires living cells.

unloading In phloem, the process of transferring sugars and other molecules in phloem to adjacent

Sucrose and other solutes can move from the mesophyll cells into the phloem by either an apolastic pathway or a symplastic pathway. In the apolastic pathway, sucrose and other solutes leave the mesophyll cells and enter the apoplast before they reach the sieve tube elements. Specific sugars and amino acids are then actively transported into cells of the phloem. Because the solutes cross at least one selectively permeable membrane in the apolastic pathway, selective transport can be used to regulate which specific substances enter the phloem. In the symplastic pathway, the solutes remain within the symplast all the way from the mesophyll cells to the sieve tube elements. Because no membranes are crossed in the symplastic pathway, a mechanism that does not involve membrane transport is used to load sucrose into the phloem.

In sink regions, the solutes are actively transported *out* of the sieve tube elements and into the surrounding tissues. This unloading serves several purposes: it helps maintain the gradient of solute potential, and hence of pressure potential, in the sieve tubes; it helps build up high concentrations of carbohydrates in storage organs, such as developing fruits and seeds; and it moves nutrients to parts of the plant that are growing rapidly, such as shoots that form after the winter.

[Table 34.2](#) contrasts the pressure flow model of translocation in the phloem with the transpiration-cohesion-tension model of xylem transport.

table 34.2 Mechanisms of Sap Flow in Plant Vascular Tissues

	Xylem	Phloem
Driving force for bulk flow	Transpiration from leaves	Active transport of sucrose at source and sink
Site of bulk flow	Nonliving vessel elements and tracheids	Living sieve tube elements
Pressure potential in sap	Negative (pull from top; tension)	Positive (push from source; pressure)

The control of phloem sap travel from source to sink has great importance for people. The parts of plants that we use for food, such as seeds (e.g., the rice in the opening story), fruits, and storage organs, are mostly sinks. Increasing the flow of sucrose into these organs as they develop can increase food production in crop plants.

34.4 recap

Carbohydrates produced by photosynthesis are translocated from source to sink through the phloem by a pressure flow mechanism.

learning outcomes

You should be able to:

- Define and identify sources and sinks in plants as they relate to the products of photosynthesis.
- Explain why energy and active transport are required to transport phloem sap and how the pressure flow model makes phloem sap flow possible.
- Define and compare the processes of loading and unloading in phloem sap transport.

1. Explain the difference between a source and a sink.
2. How does loading of sucrose at the source result in bulk flow toward the sink?

investigatinglife

QA What methods are used to reduce water loss in agriculture?

Ensuring the availability of water and its dissolved nutrients is a challenge to growing our crops. Historically, the approach of farmers has been to grow crops adapted to the local environment (e.g., heavy rainfall for rice) or adapt the environment for the plant (irrigation). With our changing climate resulting in droughts, a new approach—adapting the plant's genetic ability to the environment—has begun. The *HARDY* gene, described in *Investigating Life: Improving Water-Use Efficiency in Rice*, confers adaptation to drought in rice plants by upregulating the expression of clusters of genes involved in water-use efficiency, the ratio of plant biomass produced to water transpired. This is largely achieved through increased leaf thickness, with more mesophyll cells resulting in increased photosynthesis, as well as increased root growth, for greater uptake of water from the soil. The *HARDY* gene acts during development of leaves and roots, which you will recall happens throughout the life of the plant.

Future directions

Sorghum bicolor is an important grain crop worldwide, grown for human food, animal feed, and as a source for biofuels. It is especially valuable because it is both drought- and heat-tolerant, and so is important in hot, dry regions in Africa and South America. At the University of Illinois, scientists are trying to improve the water-use efficiency of sorghum by reducing transpiration in two ways: reduction of leaf stomata and shifting more photosynthesis to lower leaves, which are nearer to the ground and thus surrounded by humid air. Thousands of varieties of sorghum are stored in "seed banks." Samples of these seeds will be germinated and grown in the search for the two desired phenotypes. In addition, a deliberate molecular approach using transgenic plants will be attempted. It is hoped that the result will be a crop even better adapted to make the best use of limited water.

► 34.1 Plants Acquire Water and Minerals from the Soil

- Water moves through biological membranes by osmosis, always moving toward regions with a more negative water potential. The **water potential** (Ψ) of a cell or solution is the sum of the **solute potential** (Ψ_s) and the **pressure potential** (Ψ_p). **Review Figure 34.2, Activity 34.1**

water potential (Ψ , psi) In osmosis, the tendency for a system (a cell or solution) to take up water from pure water through a differentially permeable membrane.

solute potential (Ψ_s) A property of any solution, resulting from its solute contents; it may be zero or have a negative value. The more negative the solute potential, the greater the tendency of the solution to take up water through a differentially permeable membrane. (Contrast with pressure potential, water potential.)

pressure potential (Ψ_p) The hydrostatic pressure of an enclosed solution in excess of the surrounding atmospheric pressure. (Contrast with solute potential, water potential.)

- Turgid** plant cells have significant positive pressure potential because the rigid cell wall limits expansion of the cell. This positive pressure (**turgor pressure**) maintains the physical structure of many plant cells; if the pressure potential drops, the plant wilts.

turgid Swollen or distended. In plants, a cell is turgid when its water potential is lower than that of the surrounding environment.

- The movement of a solution due to a difference in pressure potential between two parts of a plant is called **bulk flow**.

bulk flow The movement of a solution from a region of higher pressure potential to a region of lower pressure potential.

- Aquaporins are channel proteins that facilitate movement of water molecules through biological membranes.
- Mineral uptake requires transport proteins. Some minerals enter the plant passively by facilitated diffusion; others enter by active transport. A **proton pump** provides energy for the active transport of many mineral ions across membranes in plants. **Review Figure 34.4**

proton pump An active transport system that uses ATP energy to move hydrogen ions across a membrane, generating an electric potential.

- Water and minerals pass from the soil into the root by way of the **apoplast** and **symplast**, but must pass through the symplast to cross the endodermis and enter the xylem. The

Casparian strip in the endodermis blocks movement of water and minerals through the apoplast. **Review** [Figures 34.5](#), [34.6](#), [Activity 34.2](#)

apoplast (ap' oh plast) In plants, the continuous meshwork of cell walls and extracellular spaces through which material can pass without crossing a plasma membrane. (Contrast with symplast.)

symplast The continuous meshwork of the interiors of living cells in the plant body, resulting from the presence of plasmodesmata. (Contrast with apoplast.)

Casparian strip A band of cell wall containing suberin and lignin, found in the endodermis. Restricts the movement of water across the endodermis.

► 34.2 Water and Minerals Are Transported in the Xylem

- Experiments proved that neither a root pump nor capillary action can alone account for the ascent of xylem sap in trees.
- Water transport in the xylem results from the combined effects of [transpiration](#), cohesion, and tension—the transpiration-cohesion-tension mechanism. Evaporation from the leaf produces tension in the mesophyll cells, which pulls a column of water—held together by cohesion—up through the xylem from the root. **Review Focus: Key** [Figure 34.7](#), [Animation 34.1](#)

transpiration [L. *spirare*: to breathe] The evaporation of water from plant leaves and stem, driven by heat from the sun, and providing the motive force to raise water (plus mineral nutrients) from the roots.

- Transport in the xylem is passive. It does not require the expenditure of energy by the plant.
- Water-use efficiency is the ratio of plant growth to water uptake.

► 34.3 Stomata Control the Loss of Water and the Uptake of CO₂

- The waxy cuticle of plant epidermis is impermeable to both water and carbon dioxide. **Stomata** allow for carbon dioxide uptake (when open) while minimizing transpirational water loss (when closed).
- A pair of [guard cells](#) controls the size of the stomatal opening. A light-activated proton pump moves protons out of the guard cells to the walls of surrounding epidermal cells, setting up an electrochemical gradient that drives the transport of potassium ions into the guard cells. Water follows osmotically, swelling the guard cells and opening the stomata. **Review** [Figure 34.8](#)

guard cells In plants, specialized, paired epidermal cells that surround and control the opening of a stoma (pore).

- When threatened by dehydration, mesophyll cells release abscisic acid, which causes guard cells to close the stomata, even in the light.

► 34.4 Solutes Are Transported in the Phloem

- Products of photosynthesis, as well as some minerals, are translocated through sieve tubes in the phloem by way of living sieve tube elements. **Review** [Figure 34.9](#)

- Translocation in the phloem can proceed in both directions in the stem. Translocation requires a supply of metabolic energy from living cells.
- Translocation in the phloem is explained by the [pressure flow model](#): the difference in solute concentration between [sources](#) and [sinks](#) creates a difference in (positive) pressure potential along the sieve tubes, resulting in bulk flow. **Review** [Figure 34.10](#), [Table 34.2](#), [Animation 34.2](#)

pressure flow model An effective model for phloem transport in angiosperms. It holds that sieve element transport is driven by an osmotically generated pressure gradient between source and sink.

source In plants, any organ that exports the products of photosynthesis in excess of its own needs, such as a mature leaf or storage organ. (Contrast with sink.)

sink In plants, any organ that imports the products of photosynthesis, such as roots, developing fruits, and immature leaves. (Contrast with source.)

Review

4.1 Water potential is determined by solute potential and pressure potential.

4.1 Movement of water and ions across a cell membrane can be impeded.

4.1 The two main pathways to get water from the soil into the xylem are the apoplast and the symplast.

Original Paper: Maurel, C., J. Reizer, J. I. Schroeder and M. J. Chrispeels. 1993. The vacuolar membrane protein γ -TIP creates water specific channels in *Xenopus* oocytes. *The EMBO Journal* 12: 2241-2247.

Most plant cells contain a large vacuole. In addition to the cell membrane, the vacuolar membrane (tonoplast) plays an important role in water relations between a plant cell and its environment. Changes in water potential in the environment can lead to changes in turgor pressure and therefore plant structure (see [Key Concept 6.3](#) and [Figure 6.10](#)). The tonoplast contains a prominent protein called TIP (tonoplast intrinsic protein), which is related in sequence to the aquaporins of animal and bacterial cells.

Researchers investigated the possible aquaporin function of a tonoplast TIP from *Arabidopsis thaliana* by isolating the gene for the protein and expressing its mRNA in oocytes of the frog *Xenopus laevis*. These cells are large, and their size is easily measured in the light microscope. The oocyte cell membrane normally has low osmotic permeability. The researchers injected oocytes with the mRNA of the plant TIP, which contained the 5' and 3' untranslated sequences for protein synthesis in *Xenopus*. They injected other oocytes with an mRNA of a nontransport protein, and left yet other oocytes uninjected.

After injection, all of the oocytes were incubated in isotonic medium for 2 days to allow for protein synthesis and transport. Then the oocytes were placed in hypotonic medium to increase external water potential relative to the inside of the cells. The sizes of the oocytes were measured microscopically over 4 minutes and then compared. The results are shown in the graph.

After 4 minutes in hypotonic medium, the oocytes containing TIP mRNA burst; those injected with unrelated mRNA and those that were uninjected did not burst.

The researchers then calculated the osmotic water permeability of the oocyte cell membranes during the experiment. Osmotic permeability coefficient was measured from the change in

volume and surface area of the cells and water potentials inside and outside the cells. A higher osmotic coefficient indicates greater water movement across the membrane. The results are shown in the table below.

Condition	Osmotic water permeability (10^{-2} cm/sec)
TIP mRNA injected	1.25
Unrelated mRNA injected	0.15
Uninjected	0.15

Questions

1. From the graph, what can you conclude about the possible role of TIP? Why were the other two conditions important to your interpretation?
2. Why did the TIP-containing oocytes burst in the hypotonic environment? Would this have happened if the researchers had injected plant cells with TIP mRNA?
3. How do the data in the table relate to those in the figure?
4. Since the original discovery of the first plant aquaporin TIP, numerous related proteins have been found in plants. Some are in the cell membrane (plasma intrinsic proteins, or PIPs). If you examined a root in cross-section and stained it specifically for PIPs, where would you expect these proteins to be most prominent in the apoplastic and symplastic pathways?
5. In the growing root tip (see [Figure 33.10](#)), cells elongate considerably. This elongation is driven primarily by uptake of water by the cells and their prominent central vacuoles. How would you investigate the role of aquaporins in the uptake of water in these cells?

Plant Nutrition

Corn plants, such as those being fertilized here, extract a lot of nitrogen compounds from the soil. Excess nitrogen the corn plants do not take up gets left behind in the soil, where it can be a pollutant.

- [5.4 Soil Organisms Increase Nutrient Uptake by Plant Roots](#)

investigatinglife

Improving Plant Nutrition to Feed the World

Crops such as rice, wheat, and corn supply more than half of the human diet. Plants require good nutrition in order to grow and one of the nutrients often in short supply in soils is nitrogen. Organic farmers traditionally supply nitrogen by spreading animal waste (manure) over the field; as nature takes its course, the complex macromolecules in manure are broken down to ammonium (NH_4^+).

In 1917, Fritz Haber and Carl Bosch invented a way to make ammonia in the factory, revolutionizing crop plant nutrition. The Haber–Bosch process has been called one of the most important scientific feats of the twentieth century. Chemical fertilizer in the form of ammonium salts led to spectacular increases in food production. But nitrogen fertilizer is expensive in two ways. First, the Haber–Bosch process of manufacturing ammonium from hydrogen and nitrogen gases is very energy intensive and costly.

Second, nitrogen fertilizer is also environmentally expensive. When it rains excessively, nitrogen fertilizer can be lost from farm fields and end up in lakes, rivers, or groundwater. When nitrogen-laden rivers enter the sea, excessive growth of marine algae is likely to result. Eventually the algae die, and the organisms that decompose the algae use up so much oxygen in the water that there is not enough left to support marine life. Nitrogen fertilizer runoff has resulted in vast "dead zones" in waters near the mouths of major rivers, including the Mississippi River Delta in the Gulf of Mexico. An additional environmental cost is the conversion of some nitrogen fertilizer to nitrous oxide gas (N_2O), which contributes to global warming.

Scientists are working on several strategies by which nitrogen fertilizer might be used more efficiently. One strategy is to improve farming practices, by applying optimal rates of nitrogen to crops while reducing losses to the environment. The other strategy is to alter the genetics of crop plants to improve their uptake and assimilation of nitrogen. Many processes are involved in a plant's use of nitrogen from the soil, such as uptake into the roots, transport to other organs in the vascular system, and incorporation of nitrogen into organic molecules such as amino acids and nucleotides. Each process involves many genes, underscoring the complexity of inheritance.

How can nitrogen use efficiency be improved?

35.1 Plants Require Nutrients

Every living thing—and a plant is no exception—must obtain raw materials from its environment. These **nutrients** include the major ingredients of macromolecules: carbon, hydrogen, oxygen, and nitrogen. Plants are autotrophs, and obtain both carbon and oxygen from the atmosphere through the reactions of photosynthesis and cellular respiration (see [Chapters 9](#) and [10](#)). Hydrogen comes mainly from water, so it is plentiful when there is an adequate water supply. Nitrogen, as you will see later in this chapter, enters most plants from the soil. The activities of microorganisms are important in converting organic nitrogen and nitrogen gas into inorganic forms that are usable by plants.

nutrient A food substance; or, in the case of mineral nutrients, an inorganic element required for completion of the life cycle of an organism.

focus your learning

Plants receiving insufficient quantities of essential elements can be evaluated by observing symptomatic changes in physical features and/or growth.

Experiments using hydroponic growth conditions have allowed scientists to determine the essential elements plants need for growth.

In addition to nitrogen, organisms require other **mineral nutrients**: inorganic elements that are used for various cellular processes. For example, proteins contain sulfur (S), nucleic acids contain phosphorus (P), chlorophyll contains magnesium (Mg), cytochromes contain iron (Fe), and cellular signaling can involve calcium (Ca). Most plants obtain these nutrients from the soil. Within the soil, minerals dissolve in water as ions, forming a solution—called the **soil solution**—that contacts the roots of plants.

mineral nutrients Inorganic ions required by organisms for normal growth and reproduction.

soil solution The aqueous portion of soil, from which plants take up dissolved mineral nutrients.

Plants require nutrients in different amounts

A plant nutrient is called an **essential element** if the plant fails to complete its life cycle or grows abnormally when the element is absent or insufficient. Essential elements ([Table 35.1](#)) fall roughly into two categories—macronutrients and micronutrients—based on the amounts required by plants.

A plant needs **macronutrients** in concentrations of at least 1 gram per kilogram of the plant's dry matter.

A plant needs **micronutrients** in concentrations of less than 100 milligrams per kilogram of the plant's dry matter.

essential element A mineral nutrient required for normal growth and reproduction in plants and animals.

macronutrient In plants, a mineral element required in concentrations of at least 1 milligram per gram of plant dry matter; in animals, a mineral element required in large amounts. (Contrast with micronutrient.)

micronutrient In plants, a mineral element required in concentrations of less than 100 micrograms per gram of plant dry matter; in animals, a mineral element required in concentrations of less than 100 micrograms per day. (Contrast with macronutrient.)

table 35.1 Mineral Elements Required by Plants

Element (abbreviation; absorbed form)	Typical amount in plant (g/kg dry wt)	Major functions	Deficiency symptoms
Macronutrients			
Nitrogen (N; NO ₃ ⁻ and NH ₄ ⁺)	15	In proteins, nucleic acids	Oldest leaves turn yellow and die prematurely; plant is stunted
Phosphorus (P; H ₂ PO ₄ ⁻ and HPO ₄ ²⁻)	2	In nucleic acids, ATP phospholipids, and phosphoproteins	Plant is dark green with purple veins and is stunted
Potassium (K; K ⁺)	10	Enzyme activation; water balance; ion balance; stomatal opening	Older leaves have dead edges
Sulfur (S; SO ₄ ²⁻)	1	In proteins and coenzymes	Young leaves are yellow to white with yellow veins
Calcium (Ca; Ca ⁺)	5	Affects the cytoskeleton, membranes, and many enzymes; second messenger	Growing points die back; young leaves are yellow and crinkly
Magnesium (Mg; Mg ⁺)	2	In chlorophyll; required by many enzymes; stabilizes ribosomes	Older leaves have yellow stripes between veins
Micronutrients			
Iron (Fe; Fe ⁺ and Fe ²⁺)	0.1	In active site of many redox enzymes and electron carriers; chlorophyll synthesis	Young leaves are white or yellow
Chlorine (Cl; Cl ⁻)	0.1	Photosynthesis; ion balance	Leaf tips wilt; leaves turn yellow and die
Manganese (Mn; Mn ⁺)	0.05	Cofactor for many enzymes	Younger leaves are pale with green veins
Boron [B; B(OH) ₃]	0.02	Required for proper cell wall formation and expansion	Poor growth of leaves and roots
Zinc (Zn; Zn ⁺)	0.02	Enzyme activation; auxin synthesis	Young leaves are abnormally small; older leaves have many dead spots

Copper (Cu; Cu ^{0.006} +)	Cofactor for some redox enzymes and electron carriers	New leaves are dark green, may have dead spots
Nickel (Ni; Ni ^{0.001} +)	Activation of the enzyme urease	Leaf tips die; deficiency is rare
Molybdenum (Mo; MoO ₄ ²⁻ 0.0001)	Cofactor of enzymes involved in nitrogen reduction	Leaves turn yellow between veins; older leaves die

How do we know if a plant is getting enough of a particular nutrient?

Deficiency symptoms reveal inadequate nutrition

When a plant is deficient in an essential element, it displays characteristic **deficiency symptoms**. [Table 35.1](#) and [Figure 35.1](#) describe some of the symptoms that help growers diagnose mineral nutrient deficiencies in plants. With proper diagnosis, the missing nutrient(s) can be provided in the form of a **fertilizer** (an added source of mineral nutrients).

fertilizer Any of a number of substances added to soil to improve the soil's capacity to support plant growth. May be organic or inorganic.

Figure 35.1 Mineral Nutrient Deficiency Symptoms Deficiencies of several nutrients are depicted in this diagram. Of course, it is very unlikely that a single plant would show all of these symptoms.

Animation 35.1 **Nitrogen and Iron Deficiencies** www.Life11e.com/a35.1

Hydroponic experiments identified essential elements

The essential elements for plants were identified by growing plants **hydroponically**—that is, with their roots suspended in nutrient solutions instead of soil. Growing plants in this manner allows for greater control of nutrient availability than is possible in a complex medium such as

soil.

hydroponic Pertaining to a method of growing plants with their roots suspended in nutrient solutions instead of soil.

In the first experiments of this type, performed a century and a half ago, plants seemed to grow normally in solutions containing only calcium nitrate $[\text{Ca}(\text{NO}_3)_2]$, magnesium sulfate (MgSO_4), and potassium phosphate (KH_2PO_4). A solution missing any of these compounds could not support normal growth. Tests with other compounds that included various combinations of these elements soon established the existence of six essential elements: calcium, nitrogen, magnesium, sulfur, potassium, and phosphorus. These are now known as the essential mineral macronutrients.

Iron was the first micronutrient to be clearly established as essential, in the 1840s. The most recent micronutrient to be listed as essential was nickel, in 1983. Identifying essential micronutrients proved to be more difficult than identifying macronutrients because of the small amounts involved. Sufficient amounts of micronutrients can be present in the environment used to grow plants or in the plants themselves. A seed may contain enough of a micronutrient to supply the embryo and the entire plant throughout its lifetime. There might even be enough left over to pass on to third-generation plants. Because of such difficulties, nutrition experiments must be performed in tightly controlled laboratories with special air filters that exclude microscopic salt particles in the air, and must use only the purest available chemicals.

You have seen that plants require a specific set of nutrients in large and small amounts for optimal growth and development. let's look at how a plant finds and takes up these nutrients from its environment.

35.1 recap

Plants are autotrophs that obtain carbon and oxygen by photosynthesis, and mineral nutrients and water from the soil. Nutrients required by plants are classified as either macronutrients or micronutrients depending on the amount needed. Micronutrients are often needed in such minute amounts that only sophisticated chemical experiments can determine their essentiality.

learning outcomes

You should be able to:

- Identify nutrient deficiencies based on observations.
- Explain difficulties involved in testing nutrient requirements for plant growth.

-
1. Methods for determining whether a particular element is essential for plant growth were established a century and a half ago, yet the essentiality of some elements was discovered only recently. Why?
 2. If the young leaves of a plant are yellow, what nutrient deficiencies may be suspected? What if the yellow leaves are the oldest ones?

35.2 Plants Acquire Nutrients from the Soil

We can move from place to place to find the nutrients we need. But a plant cannot change its location (it is sessile), and so must obtain nutrients from its immediate environment. With the exception of carbon and oxygen, a plant's supply of nutrients is strictly local, and a plant may use up the water and mineral nutrients in its local environment as it grows. How does a plant cope with the problem of scarce nutrient supplies?

focus your learning

Plants alter their direction of root growth, depending on the availability of dissolved nutrients in the soil.

Plant cells use gene regulation to control the numbers of membrane transporters and enzyme regulation to control the rate of incorporation of nutrients into complex biomolecules.

Plants rely on growth to find nutrients

As you learned in [Chapter 33](#), plants differ fundamentally from animals in that plants grow throughout their lifetimes. In fact, growth is a plant's version of movement. For example, roots obtain most of the mineral nutrients plants need. By growing through the soil, roots mine it for new sources of mineral nutrients and water. The growth of stems and leaves helps a plant secure light and carbon dioxide, which in turn allows the roots to continue their growth through the soil. Deficiencies in water or specific mineral nutrients can stimulate plants to grow more roots, to improve the plants' chances of finding the nutrients they need.

As it grows, a plant—or even a single root—must deal with a variable environment. Animal droppings create high local concentrations of nitrogen. A particle of calcium carbonate may make a tiny area of the soil alkaline, while dead organic matter may make a nearby area acidic. Such microenvironments encourage or discourage the proliferation of a root system and help direct its growth. A major effort is underway to identify the signals in the soil and signaling pathways in the root that result in growth toward a source of nutrients ([Figure 35.2](#)).

Figure 35.2 Plants Regulate Their Nutrition Plant roots branch and grow toward nutrients. Nutrients are taken up by transport proteins in the epidermal cell membrane. The number of transporters for a given nutrient can be regulated in response to nutrient availability.

Nutrient uptake and assimilation are regulated

Nutrients must cross the cell membranes of cells in order to be used in the cell or be incorporated into larger molecules. Polar molecules, including mineral ions, cross the membrane via specialized transport systems. In [Chapter 34](#) you saw how water and ions move into plant roots by way of the apoplast (through cell walls and intercellular spaces) or symplast (directly through cells). The Casparian strip prevents water and ions from entering the xylem tissues of the roots (see [Key Concept 34.1](#)); therefore these nutrients must enter the symplast before they can be transported to other tissues. In most cases, ions are actively transported across the cell membrane of epidermal cells into the symplast because their concentrations in the soil solution are generally lower than their concentrations inside cells.

Plants have specialized transport systems for the uptake of specific ions (see [Figure 35.2](#)). For example, *Arabidopsis thaliana* has more than 50 genes that encode nitrate (NO_3^-) transporters, 6 genes encoding ammonium (NH_4^+) transporters, and at least 4 genes for phosphate (PO_4^{3-}) transporters. Nutrient uptake is highly regulated because the levels of ions inside cells must be maintained at constant levels. The genes for ion transporters are regulated at the transcriptional level by the amounts of each nutrient inside cells: low nutrient levels stimulate transcription, whereas high levels repress transcription. In addition, the transporter proteins themselves are regulated (for example, by phosphorylation) to control their ion transport activity.

The incorporation of nutrients into more complex molecules is also regulated according to the plant's needs. The enzymes involved in incorporating nitrate and ammonium into amino acids are regulated at the transcriptional and posttranscriptional levels to increase assimilation when available nitrogen is abundant. The uptake and assimilation of nitrogen are also stimulated by photosynthesis, and this ensures that the nitrogen status in the plant is coordinated with its carbon status.

Plants acquire many essential elements from the soil. As you will see in the next section, soils have complex structures that affect the availability of nutrients for plants.

35.2 recap

Both the uptake and assimilation of nutrients are regulated according to a plant's needs.

learning outcomes

You should be able to:

- Explain how growth is involved in a plant's search for nutrients.
- Describe how a plant is able to control the rate of movement of nutrients into a cell.

1. How do plants control the uptake and assimilation of mineral nutrients?
2. How does the ability to grow throughout their lifetimes allow plants to seek out nutrients?

35.3 Soil Structure Affects Plant Nutrition

Most terrestrial plants grow in soil. Soils provide:

Mechanical support

Mineral nutrients and water from the soil solution

O₂ for root respiration

Soils also harbor many bacteria and other organisms; some of these are beneficial to plant life, but others are harmful. Some soils contain toxic levels of metal ions such as cadmium, chromium, and lead.

focus your learning

Soil can vary greatly in its composition of particles and nutrient availability (fertility). Most soils consist of three major horizons.

Uptake of minerals that exist as cations in soil water is facilitated by a cation exchange process under slightly acidic pH conditions.

The fertility of depleted and leached soils can be improved by adding organic and inorganic fertilizers.

Soils are modified by natural phenomena such as rain, temperature extremes, and the activities of plants and animals. They are also modified by the activities of people, particularly in agriculture. In this section you'll learn about the composition, structure, and formation of soils, as well as their role in plant nutrition.

Soil provides anchorage and nutrients for plants

Soils have living and nonliving components (**Figure 35.3**). The living components include plant roots as well as populations of bacteria, fungi, protists, and animals such as earthworms and insects. The nonliving portion of the soil includes rock fragments ranging in size from large stones to sand to silt, and finally to tiny particles of clay that are 2 micrometers (μm) or less in diameter. Soil also contains water and dissolved mineral nutrients, air spaces, and dead organic matter. The air spaces in soil contain O₂. Typical percentages of these components are:

soils The upper layers of Earth's surface that support plant growth.

Particles: 45% Water: 25% Air: 25% Organisms: 5%

Figure 35.3 The Complexity of Soil Soils favorable for plant growth contain both clay and larger mineral particles, as well as water, air, and organic matter. Other organisms are also present.

Although soils vary greatly, almost all of them have a soil profile consisting of several recognizable horizontal layers, called **horizons**, lying on top of one another. Soil scientists recognize three major horizons—termed A, B, and C—in the profile of a typical soil (**Figure 35.4**).

horizons The horizontal layers of a soil profile, including the topsoil (A horizon), subsoil (B horizon) and parent rock or bedrock (C horizon).

Figure 35.4 A Soil Profile The A, B, and C horizons can sometimes be seen at construction sites such as this one in Massachusetts. The upper layer (the A horizon) is home to most of the living organisms in the soil.

The **A horizon** is the **topsoil** that supports the plant's nutrient needs. It contains most of the soil's living and dead organic matter.

A horizon See topsoil.

topsoil The uppermost soil horizon; contains most of the organic matter of soil, but may be depleted of

most mineral nutrients by leaching. Also called the A horizon.

The **B horizon** is the **subsoil**, which accumulates materials from the topsoil above it and from the parent rock below.

B horizon See subsoil.

subsoil The soil horizon lying below the topsoil and above the parent rock (bedrock); the zone of infiltration and accumulation of materials leached from the topsoil. Also called the B horizon.

The **C horizon** is the **parent rock**, also called bedrock, which is in the process of breaking down to form soil.

C horizon See parent rock.

parent rock The soil horizon consisting of the rock that is breaking down to form the soil. Also called bedrock, or the C horizon.

Soil fertility is a soil's ability to support plant growth. A topsoil's fertility is determined by several factors. Topsoils vary greatly in their proportions of sand, silt, and clay, and this influences their ability to support plant growth. For example, mineral nutrients tend to be **leached** from the upper soil horizons—dissolved in rain or irrigation water and carried to deeper horizons, where they are unavailable to plant roots. Dissolved minerals are readily leached from sandy soil because sand particles are relatively large and cannot hold water. Clay, by contrast, binds more water than sand does, and the charged surfaces of clay particles bind mineral ions that plant roots ultimately take up. But clay particles are tiny and pack tightly together, leaving little space for air. A **loam** is a soil that is an optimal mixture of sand, silt, and clay and thus has sufficient levels of air, water, and available nutrients for plants. Loams also usually contain organic matter. Most of the best topsoils for agriculture are loams.

soil fertility The ability of a soil to sustain plant growth, in terms of the soil's concentration of available plant nutrients.

loam A type of soil consisting of a mixture of sand, silt, clay, and organic matter. One of the best soil types for agriculture.

In addition to mineral particles, soils contain dead organic matter, largely from plants. Soil organisms break down dead leaves and other plant organs on the ground into a substance called **humus**. This material is used as a food source by microbes that break down complex organic molecules and release simpler molecules into the soil solution. Humus also provides air spaces that increase O₂ availability to plant roots.

humus (hew' mus) The partly decomposed remains of plants and animals on the surface of a soil.

Soils form through the weathering of rock

Rocks are broken down into soil particles—**weathered**—in two ways. First, there is *mechanical weathering*, which is the physical breakdown of materials by wetting, drying, and freezing. Second, there is *chemical weathering*, the alteration of the chemistry of the materials in the

rocks. Several types of chemical weathering occur, all of which influence the availability of mineral nutrients:

weathered The mechanical and chemical processes by which rocks are broken down into soil particles.

Oxidation by atmospheric oxygen

Hydrolysis (reaction with water)

Reaction with acids (particularly carbonic acid)

The parent rock and the weathering it undergoes determine the basic structure and chemical composition of a soil. However, a key soil characteristic for plants is the availability of nutrients, which must be dissolved in the soil solution for uptake by the plant. Chemical weathering often results in clay particles that are covered with negatively charged chemical groups, which bind positively charged mineral nutrients. How might roots obtain these mineral nutrients?

Soils are the source of plant nutrition

Humus and clay particles often carry negative charges. These particles form ionic attractions (see [Key Concept 2.2](#)) with the positively charged ions (cations) of many minerals that are important for plant nutrition, such as potassium (K^+), magnesium (Mg^{2+}), and calcium (Ca^{2+}). To become available to plants or other organisms, these cations must be detached from the clay particles. How can this breakage of ionic attraction happen?

Recall that the root surface is covered with root hair cells (see [Figure 33.10](#)). Transporters in the cell membranes of these cells actively pump protons (H^+) out of the cell. In addition, cellular respiration in the roots releases CO_2 , which dissolves in the soil water and reacts with it to form carbonic acid. This acid ionizes to form bicarbonate and free protons:

Proton-pumping by the root and ionization of carbonic acid both act to increase the proton concentration (lower the pH) in the soil surrounding the root. The protons bind more strongly to clay particles than do mineral cations; in essence, they trade places with the cations in a process called [cation exchange](#) ([Figure 35.5](#)). Cation exchange releases important cations into the soil solution, where they are available to be taken up by the roots. Soil fertility is determined in part by the soil's ability to provide nutrients in this manner.

cation exchange The process in soil by which cations bound to soil particles are released from the particles and made available to plant roots in soil water through the binding of hydrogen ions to the soil particles.

Figure 35.5 Cation Exchange Plants obtain mineral nutrients from the soil primarily in the form of positive ions; potassium (K^+) is the example shown here.

Q: Do negatively charged ions behave differently?

Some soil particles, such as ones containing oxides of iron or aluminium, are positively charged under acid conditions and can exchange anions (Cl^- , for example) in a process similar to cation exchange. However, soil pH is rarely low enough for anion exchange to occur. As a result, important anions such as nitrate (NO_3^-) and sulfate (SO_4^{2-})—direct sources of nitrogen and sulfur, respectively—may leach rapidly from the A horizon.

As you've seen, soil fertility is affected by soil pH. The H^+ concentration affects the binding of cations and anions to soil particles, and can affect the solubility of other nutrients, such as iron. In addition, soil pH affects the absorption of nutrients by plant roots. The pH level of a soil depends on its mineral and organic contents and can be altered by various factors, including rainfall, weathering, plant growth, and fertilizer applications. The optimal soil pH for most plants is in the range 6-7.5, but some plants, such as blueberries and cranberries, prefer pH levels of 4.5-5.

Fertilizers add nutrients to soil

Leaching and the harvesting of crops can deplete a soil of its nutrients, so that new crops grow poorly on that soil. Soil fertility can be restored or increased in various ways, including shifting agriculture to another location or applying organic or chemical fertilizers.

SHIFTING AGRICULTURE

In the past, when the soil could no longer support a level of plant growth sufficient for agricultural purposes, people simply moved to another location. The nutrients in the soil of a field allowed to lie fallow will be replenished gradually through the addition of organic matter from the growth and death of plants naturally present, and by the weathering of the parent rock. Both processes take a long time, which is not a problem as long as a lot of land is available. Today, however, the food needs of a large human population are too great to allow land to be left vacant for a long time, and people are disinclined to move away from settled homesteads. As a consequence, chemical fertilizers are often used to improve soil fertility.

ORGANIC FERTILIZERS

Microorganisms in the soil break down organic molecules into smaller, simpler molecules. These

simpler molecules can dissolve in soil water and enter plant roots. For example, soil bacteria break down the proteins in dead leaves and produce ammonium ions (NH_4^+), which in turn are converted into nitrate (NO_3^-). Both ammonium and nitrate can be taken up and used by plants:

protein in leaves $\rightarrow$ Bacteria NH_4^+ $\rightarrow$ Bacteria NO_3^- + *protein in leaves* $\xrightarrow{\text{Bacteria}}$ NH_4^+ $\xrightarrow{\text{Bacteria}}$ NO_3^-

Farmers can increase the nutrient content of soil by adding organic materials such as compost (partially decomposed plant materials) or manure (waste from farm animals). Manure is a particularly good source of nitrogen. In either case, the addition of these **organic fertilizers** adds nutrients to the soil much more rapidly than weathering or the gradual addition of organic matter from natural vegetation. Organic fertilizers allow for a slow release of ions as the materials decompose.

organic fertilizers Substances added to soil to improve the soil's fertility; derived from partially decomposed plant material (compost) or animal waste (manure).

INORGANIC FERTILIZERS

Organic fertilizers may act too slowly to restore fertility if a soil is to be used every year. As you read in the opening investigation of this chapter, **inorganic fertilizers** supply mineral nutrients in forms that can be taken up immediately by plants or that are rapidly converted to usable forms in the soil. Inorganic fertilizers are easily transported and handled, and allow farmers to control the amount of a particular nutrient that is supplied to each crop. Particular fertilizers are used in varying amounts, depending on the needs of the crop and the type of soil. For example, much higher amounts of nitrogen are applied to cornfields than to soybean fields. Inorganic fertilizers come in many forms. Common ones include ammonia (NH_3), urea ($\text{NH}_2 - \text{CO} - \text{NH}_2$), and salts formed from positive and negative ions such as ammonium (NH_4^+), potassium (K^+), nitrate (NO_3^-), phosphate (PO_4^{3-}), and sulfate (SO_4^{2-}).

inorganic fertilizer A chemical or combination of chemicals applied to soil or plants to make up for a plant nutrient deficiency. Often contains the macronutrients nitrogen, phosphorus, and potassium (N-P-K).

35.3 recap

Land plants live anchored in the soil and obtain water and mineral nutrients from it. Soils are complex in structure and vary in fertility. Farmers can add fertilizers to improve the nutrient contents of soils.

learning outcomes

You should be able to:

- Predict changes in a soil in response to environmental and land use changes.
- Explain how soil fertility is influenced by the process of cation exchange.
- Compare and contrast organic and inorganic fertilizers.

1. Soils are dynamic systems. What changes might result when land is subjected to heavy irrigation for agriculture after being relatively dry for many years? What changes in the soil

might result when a deciduous forest is cut down and replaced by crops that are harvested each year?

[2.](#) How does the process of cation exchange enhance soil fertility?

[3.](#) What are the differences between organic and inorganic nitrogen fertilizers in terms of plant nutrition?

Thus far we have focused on the uptake of nutrients in the soil by plant roots. An understanding of how plants acquire nutrients from the soil would be incomplete, however, without taking into account the involvement of soil microbes, including fungi and bacteria. In the next section we will focus on the intimate interactions of plants with these organisms, which are essential to the success of most terrestrial plants.

35.4 Soil Organisms Increase Nutrient Uptake by Plant Roots

One gram of soil can contain 6,000-50,000 bacterial *species* and up to 200 *meters* of fungal hyphae (the long branching cells of fungi), although both are largely invisible to the naked eye. In [Chapter 38](#) you will learn how plants prevent infection by harmful soil microbes. But plants actually encourage a few species of fungi and bacteria to infect their roots and even invade root cells. In this section we will describe the mutually beneficial relationships in which products are exchanged between the plants and these special soil microbes.

focus your learning

Mutualistic relationships between soil organisms and plant roots are facilitated by chemical signal exchange.

Although abundant in Earth's atmosphere, nitrogen is not a readily available nutrient for plants. Humans have used various methods, including crop rotation and use of natural and human-made fertilizers, to replenish soil nitrogen depleted by crop harvesting.

Plants send signals to soil organisms

In [Chapter 29](#) we described mycorrhizae, the association of fungi with plant roots—an interaction that occurs in more than 90 percent of terrestrial plants. Our example in [Chapter 29](#) was ectomycorrhizal fungi, which wrap themselves around a plant root (see [Figure 29.10](#)). In this chapter we examine arbuscular mycorrhizae, in which fungal hyphae penetrate root cells. We also describe here the close association between the roots of some plants and rhizobia, a group of nitrogen-fixing bacteria (bacteria that convert atmospheric N_2 into a more biologically useful form). You will see that ***mycorrhizal and rhizobial associations** are both initiated by signals sent by plant roots that attract the soil organisms, and that the development of these associations involves similar genes and cellular pathways.

FORMATION OF MYCORRHIZAL ASSOCIATIONS You can follow the events in the formation of arbuscular mycorrhizae in [Figure 35.6A](#). Plant roots produce molecules called **strigolactones** that stimulate rapid growth of fungal hyphae toward the root. In response, the fungi produce signals that stimulate expression of genes that promote symbioses with other organisms. The products of some of these genes give rise to the prepenetration apparatus (PPA), which guides the growth of the fungal hyphae into the root cortex. The sites of nutrient exchange between fungus and plant are the arbuscules, which form within root cortical cells. Despite the intimacy of this association, the plant and fungal cytoplasm never mix—they are separated by two membranes, the fungal cell membrane and the periarbuscular membrane (PAM), which is continuous with the plant cell membrane.

Figure 35.6 Roots Send Signals for Colonization Plant roots send chemical signals to arbuscular mycorrhizal fungi **(A)** and nitrogen-fixing bacteria **(B)** to stimulate colonization. (PAM = periarbuscular membrane.)

strigolactones Signaling molecules produced by plant roots that attract the hyphae of mycorrhizal fungi.

FORMATION OF NITROGEN-FIXING NODULES

A group of plants called legumes (members of the plant family Fabaceae) can form symbioses with soil bacteria in several genera collectively known as rhizobia. The legume roots release flavonoids and other chemical signals that attract the rhizobia to the vicinity of the roots ([Figure 35.6B](#)). The flavonoids also trigger the transcription of bacterial *nod* genes, the products of which synthesize Nod (nodulation) factors. These and other factors, when secreted by the bacteria, cause cells in the root cortex to divide, leading to the formation of a primary nodule meristem. This meristem gives rise to the plant tissue that constitutes the **root nodule**. Bacteria

enter the root via an infection thread, analogous to the PPA in mycorrhizal associations, and eventually reach cells inside the root nodule. There the bacteria are released into the cytoplasm of the nodule cells, enclosed in membrane vesicles similar to the PAM. Inside the vesicles, the bacteria differentiate into **bacteroids**—the form of the bacteria that can fix nitrogen.

root nodule A swelling on the root of a leguminous plant, such as the soybean, that contains nitrogen-fixing *Rhizobium* bacteria.

bacteroids Nitrogen-fixing organelles that develop from endosymbiotic bacteria.

A COMMON MECHANISM

Amazingly, it appears that nodule formation depends on some of the same genes and mechanisms that allow mycorrhizae to develop. For example, both processes involve folding in of the cell membrane to allow entry of the fungal hyphae or rhizobia. The similarities in the structures formed during the development of mycorrhizae and nodules are especially striking, considering that the symbioses involve members of two different kingdoms (fungi and bacteria) (**Figure 35.7**).

Figure 35.7 Intracellular Structures in Plant-Fungus and Plant-Rhizobium Symbioses Several steps in the development of mycorrhizae and nodules involve similar structures.

Mycorrhizae expand the root system

In many cases the roots of vascular plants cannot nutritionally support plant growth alone—they simply cannot reach all the nutrients available in the soil. Mycorrhizae expand the root surface area 10-fold to 1,000-fold, increasing the amount of soil that can be mined for nutrients. In addition, because fungal hyphae are much finer than root hairs, they can get into pores in the soil that are inaccessible to roots. In this way, mycorrhizae probe a vast quantity of soil for nutrients and deliver them into root cortical cells.

The primary nutrient that the plant obtains from a mycorrhizal interaction is phosphorus. In exchange, the fungus obtains an energy source: the products of photosynthesis. In fact, up to 20 percent of the photosynthate of terrestrial plants is directed to and consumed by arbuscular mycorrhizal fungi. Such associations are excellent examples of mutualism, an interaction between two species in which both species benefit. Mutualism is a type of symbiosis, in which two different species live in close contact for a significant portion of their life cycles. As is conveyed in **Investigating Life: Mycorrhizal Fungi Can Replace Fertilizer in Cassava Cultivation**, the relationship between mycorrhizae and plant roots can be exploited by increasing the fungal population. Many species of fungus invade roots. Identification and genetic improvement of these species is now possible, which holds great promise in improving phosphorus nutrition in important crops.

Soil bacteria are essential in getting nitrogen from air to plant cells

The essential mineral nutrient most commonly in short supply, in both natural and agricultural situations, is nitrogen. This is surprising because elemental nitrogen (N₂) makes up almost four-fifths of Earth's atmosphere. However, plants cannot use N₂ directly as a nutrient. The triple bond linking the two nitrogen atoms is extremely stable, and a great deal of energy is required to break it; thus N₂ is a highly unreactive substance.

Some prokaryotes have an enzyme that enables them to convert N₂ into a more reactive and biologically useful form by a process called **nitrogen fixation**:

This equation is simplified: actually, H₂ gas is a byproduct. **Nitrogen fixers**, including those present in root nodules, fix approximately 170 million metric tons of nitrogen per year. Humans use industrial methods to fix about 80 million metric tons per year. In addition, about 20 million metric tons per year are fixed in the atmosphere by nonbiological means such as lightning, volcanic eruptions, and forest fires. Rain brings these atmospherically formed products to the ground.

nitrogen fixers Organisms capable of fixing atmospheric N ₂ to form NH ₃ .

Two types of organisms can fix nitrogen:

- Free-living organisms living in soil and water (e.g., *Azotobacter* bacteria and *Nostoc* cyanobacteria [sometimes called blue-green algae])
- Symbiotic organisms living in other organisms (e.g., rhizobia in roots of legumes, and *Anabaena* cyanobacteria in aquatic ferns)

Nitrogenase catalyzes nitrogen fixation

Nitrogen fixation is the reduction (see [Key Concept 9.1](#)) of nitrogen gas. It proceeds by the stepwise addition of three pairs of hydrogen atoms to N₂ (**Figure 35.8**). In addition to N₂, these reactions require three things:

Figure 35.8 Nitrogenase Fixes Nitrogen Throughout the chemical reactions of nitrogen fixation, the reactants are bound to the enzyme nitrogenase. A reducing agent transfers hydrogen atoms to nitrogen, and eventually the final product — ammonia — is released. This reaction requires a large input of energy: about 16 ATPs are consumed per reaction.

Q: Why does O_2 inhibit this reaction?

- A strong reducing agent (e.g., ferredoxin) to transfer hydrogen atoms (protons and electrons) to N_2 and to the intermediate products of the reaction
- A great deal of energy, which is supplied by ATP
- The enzyme **nitrogenase**, which catalyzes the reaction

nitrogenase An enzyme complex found in nitrogen-fixing bacteria that mediates the stepwise reduction of atmospheric N_2 to ammonia and which is strongly inhibited by oxygen.

Nitrogenase is strongly inhibited by oxygen, and many nitrogen fixers are anaerobes that live in environments with little or no O_2 . But rhizobia are *aerobic* and fix nitrogen in aerobic plant roots. How can nitrogenase function under these circumstances?

Plants typically house nitrogen-fixing bacteria in root nodules. Within a nodule, O_2 is maintained at a low level that is sufficient to support respiration, but not so high as to inactivate nitrogenase. This is possible because the cytoplasm of nodule cells contains a plant-produced protein called **leghemoglobin**, which is an O_2 carrier. Leghemoglobin is a close relative of hemoglobin, the red, oxygen-carrying pigment of animals, and is thus an evolutionarily ancient molecule. Some plant nodules contain enough of it to be bright pink inside. Leghemoglobin, with its iron-containing heme groups, transports enough oxygen to the nitrogen-fixing bacteria to support their respiration, while keeping free oxygen concentrations low enough to protect nitrogenase.

leghemoglobin In nitrogen-fixing plants, an oxygen-carrying protein in the cytoplasm of nodule cells that transports enough oxygen to the nitrogen-fixing bacteria to support their respiration, while keeping free oxygen concentrations low enough to protect nitrogenase.

experiment

Original Paper: Ceballos, I., M. Ruiz, C. Fernandez, R. Pena, A. Rodriguez and I. Sanders. 2013. The *in vitro* mass-produced model mycorrhizal fungus, *Rhizophagus irregularis*, significantly increases yields of the globally important food security crop cassava. *PLoS ONE* 8(8): e70633.

Phosphorous is a plant macronutrient obtained from the soil. Unfortunately, in many tropical regions the phosphate level in the soil is inadequate to support the needs of crop production, forcing farmers to use inorganic phosphate fertilizer, which is a finite and expensive resource. The need for phosphate fertilizer poses an especially acute problem for farmers in poor, tropical regions of the world.

Mycorrhizal fungi very efficiently absorb phosphate ions from the soil. Plant roots with a symbiotic relationship with mycorrhizae obtain phosphorous, while the fungi obtain photosynthate (products of photosynthesis) from the plant. Ian Sanders and his team at the University of Lausanne in Switzerland, in collaboration with Alia Rodriguez and her team at the National University of Colombia in Bogota, investigated whether production of cassava could be increased by adding concentrated spores of mycorrhizae, thus lowering the need for phosphate fertilizer.

HYPOTHESIS ▶ Adding arbuscular mycorrhizae to the soil can replace the need for phosphate fertilizer and increase food production in cassava.

METHOD

work with the data

QUESTIONS

1. Concentrated spores of the mycorrhizal fungus *Rhizophagus irregularis* were added to fields of cassava stems tied to stakes. Control fields did not receive the spores. The experiments took place at Yopal, Colombia, in a tropical region. At various times, developing roots were examined microscopically for the presence of fungal hyphae. The results are shown in **Table A**. Storage roots were harvested after 400 days.

Table A

Days after spores were added	Percent colonization
45	40
90	45
135	47
180	49
225	40
270	62
315	82

Plot the data as percent colonization versus time (days after spores added). When did the colonization of fungi increase? Why do you think there was a lag time?

2. In a large field experiment, plots of 300 plants each were treated either with or without fungal spores, and with or without phosphate fertilizer in an amount usually needed for optimal growth (100%) or half of that (50%). The results are shown in **Table B**, as fresh weight (g) of cassava roots, the crop ($\pm$ SEM).

Table B

	No fertilizer	50% fertilizer	100% fertilizer
Fungal spores	38 (2)	40 (1)	43 (2)
No fungal spores	28 (2)	36 (3)	35 (2)

- a. Did the addition of mycorrhizal spores affect the cassava production? What is the evidence for your answer?
- b. What statistical test would you use to test for significance of the effects of fertilizer and added mycorrhizae?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

RESULTS

CONCLUSION ▶ Adding purified mycorrhizal spores increases cassava production and reduces the need for phosphate fertilizer.

Biological nitrogen fixation does not always meet agricultural needs

Crop rotation systems have been used for hundreds or thousands of years by many human civilizations. In these systems, each field is used to grow different crops in different years, with legumes (such as alfalfa, clover, peas, and beans) included in the rotation. The rotation may also include periods of grazing by farm animals. Because of their association with nitrogen-fixing bacteria, legumes can replace all or some of the nitrogen removed by grain crops such as wheat and corn. Even with these systems, however, bacterial ***nitrogen fixation** is not always

sufficient to support the needs of agriculture. Some traditional farmers used to plant dead fish along with corn; the decaying fish released nitrogen that the developing corn could use. Today farmers use inorganic nitrogen fertilizers produced through industrial nitrogen fixation to meet the food needs of a rapidly expanding human population.

Ammonia formation is the first step in nitrogen assimilation by plants

Nitrogen fixation by free-living bacteria in the soil results in the formation of ammonia (NH_3), and most of it is rapidly ionized to form ammonium (NH_4^+). The latter can be taken up by plant roots and is then used as a source of amino groups ($-\text{NH}_2$) in the formation of such molecules as amino acids and nucleotides. Soil bacteria called **nitrifiers** oxidize ammonia to nitrate ions (NO_3^-)—another form that plants can take up—by the process of **nitrification**. Soil pH affects which form of nitrogen is taken up by plants: nitrate ions are taken up preferentially under more basic conditions, and ammonium ions under more acidic ones. To use nitrate that has entered the roots, the plant must reduce it to ammonium in a process called **nitrate reduction**, which occurs in two enzyme-catalyzed steps. First, nitrate is converted to nitrite (NO_2^-) in the cytoplasm, and then nitrite is converted to ammonium in the plastids.

nitrifiers Prokaryotes that can convert ammonium into nitrate.

nitrification The oxidation of ammonia (NH_3) to nitrate (NO_3^-) in soil and seawater, carried out by chemoautotrophic bacteria (nitrifiers).

nitrate reduction The process by which nitrate (NO_3^-) is reduced to ammonia (NH_3).

Let's turn now to some special mechanisms for obtaining nutrients that have evolved in plant species with unusual lifestyles.

35.4 recap

Two mutualistic interactions with soil microbes are critical to the success of terrestrial plants. Fungi and plants form mycorrhizae, which greatly increase the soil volume that roots can scavenge for nutrients. Bacteria in soils and root nodules fix atmospheric nitrogen into forms that plants and ultimately animals can use.

learning outcomes

You should be able to:

- Describe the chemical signals exchanged between soil organisms and plant root cells.
- Justify the need for nitrogen-fixing organisms on Earth.
- Describe crop rotation and explain how it relates to plant nutrition.

1. What is exchanged between plants and fungi in mycorrhizae? Between leguminous plants and bacteria in nodules?
2. EARTH'S biosphere as we know it depends on the existence of a few species of nitrogen-fixing prokaryotes. What do you think might happen if one of these species were to become extinct? If all of them were to disappear?
3. A common cropping method is crop rotation, with corn or soybeans being rotated on a

given plot of land. Explain this in terms of plant nutrition, especially available nitrogen in the soil.

***connect the concepts** Mycorrhizal and rhizobial associations are examples of mutualism, one of the major types of interactions discussed in [Key Concept 56.1](#).

***connect the concepts** The importance of nitrogen fixation in the ecological nitrogen cycle is discussed in [Key Concept 57.1](#).

35.5 Carnivorous and Parasitic Plants Obtain Nutrients in Unique Ways

Most plants obtain their mineral nutrients from the soil solution. Carnivorous and parasitic plants are examples of plants that obtain nutrients from other sources.

focus your learning

Some plants can obtain some of their nutrients by trapping and digesting insects.

Chemical signaling between parasitic plants and their hosts is similar to chemical signaling observed in plant-bacteria and plant-fungus mutualistic relationships.

Carnivorous plants supplement their mineral nutrition

Some plants augment their nitrogen supply by capturing and digesting flies and other insects. There are about 500 of these [carnivorous plant](#) species, the best known of which are Venus flytraps (genus *Dionaea*) ([Figure 35.9A](#)), sundews (genus *Drosera*) ([Figure 35.9B](#)), and pitcher plants (genus *Sarracenia*).

carnivorous plant Plant capable of trapping and digesting animals to obtain nutrients.

(A) *Dionaea muscipula*

(B) *Drosera scorpioides*

Figure 35.9 Carnivorous Plants Some plants have adapted to nitrogen-poor environments by becoming carnivorous. **(A)** The Venus flytrap obtains nitrogen from the bodies of insects trapped inside the plant when its hinges snap shut. **(B)** Sundews trap insects on sticky hairs. Secreted enzymes will digest the carcass externally.

Media Clip 35.1 **A Venus Flytrap "Snaps to It"** www.Life11e.com/mc35.1

Carnivorous plants are typically found in boggy habitats that are acidic and nutrient-deficient. To obtain extra nitrogen, these plants capture animals, digest their proteins, and absorb the amino acids. Pitcher plants have pitcher-shaped leaves that collect small amounts of rainwater. Insects and even small rodents are lured into the pitchers by bright colors or attractive scents and are prevented from leaving by stiff, downward-pointing hairs. The animals eventually die and are digested by a combination of plant enzymes and bacteria in the water. Sundews have leaves covered with hairs that secrete a sticky, sugary liquid. Insects become stuck to these hairs, and more hairs curve over to further entrap them. Enzymes secreted by the plant digest the insects. Venus flytraps have specialized leaves with two halves that fold together. When an insect touches special hairs called trigger hairs on the leaf, its two halves snap together. The spiny margins interlock and imprison the insect before it can escape. The leaf then secretes enzymes that digest its prey.

The closing of the Venus flytrap's leaf is one of the fastest movements in the plant world, requiring only 0.1 seconds. To find out how this happens, Dr. Lakshminarayanan Mahadevan and colleagues at Harvard University painted fluorescent dots on the surface of the flytrap's leaf surface and used high-speed cameras to record the trap snapping shut when its trigger hairs were touched. They then used computer analysis of the recorded dot movements to generate a mathematical model to help explain the movement. The researchers found that the first step is the osmosis-driven elongation of cells on the outer surface of the leaf. The expansion of only one side of the leaf causes it to snap from a convex into a concave shape, much like a contact lens flipping inside out.

Carnivorous plants photosynthesize and extract soil nutrients just like other plants, but eating insects helps them grow faster in their natural habitats. They use the additional nitrogen from the insects to make more proteins, chlorophyll, and other nitrogen-containing compounds.

Parasitic plants take advantage of other plants

Approximately 1 percent of flowering plant species derive some or all of their water, mineral

nutrients, and sometimes even photosynthesize from other plants. These [parasitic plants](#) have evolved absorptive organs called **haustoria**, which invade the host and tap into the vascular tissues in the root or stem.

parasitic plants Plants that obtain some of their nutrition by growing on other plants.

Parasitic plants are divided into two broad classes based on their nutritional interactions with their hosts. [Hemiparasites](#) can still photosynthesize but derive water and mineral nutrients from the living bodies of other plants. Perhaps the most familiar hemiparasites are the several genera of mistletoes. Mistletoes are green and carry on some photosynthesis, but they parasitize other plants for water and mineral nutrients and may derive photosynthetic products from them as well. Dwarf mistletoe (*Arceuthobium americanum*) is a serious parasite in forests of the western United States, destroying more than 3 billion board feet of lumber per year.

hemiparasite A parasitic plant that can photosynthesize, but derives water and mineral nutrients from the living body of another plant. (Contrast with holoparasite.)

[Holoparasites](#) are completely parasitic and do not perform photosynthesis. They are taxonomically and morphologically diverse. Some, such as members of the dodder family, are plantlike in appearance, with small leaf remnants and flowers ([Figure 35.10](#)). Some holoparasites do not have leaves or stems because they spend most of their life cycle underground and only break the surface to flower.

holoparasite A fully parasitic plant (i.e., one that does not perform photosynthesis). (Contrast with hemiparasite.)

Figure 35.10 A Parasitic Plant Tendrils of dodder (genus *Cuscuta*) wrap around a mugwort (genus *Artemisia*). The parasitic dodder obtains water, sugars, and other nutrients through tiny, rootlike protuberances that penetrate the surface of the host plant.

Several parasitic plant species lack many of the genes normally present in the chloroplast genome (which in turn is only a remnant of the genome of the original endosymbiont from which the chloroplast evolved; see [Key Concepts 5.5](#) and [26.1](#)). These genes, which are needed for photosynthesis, have been lost because there is no evolutionary pressure to retain them. Thus while the parasitic lifestyle can be viewed as a free ride, for some plants it is also a one-way ticket, with no possibility of return to self-sufficiency.

The plant-parasite relationship is similar to plant-fungus and plant-bacteria associations

Plant-bacteria and plant-fungus associations both involve reciprocal signaling between the two species (see [Figure 35.6](#)). Parasitic plants also need to detect signals from nearby plants so they can grow toward them and obtain their nutrients, but obviously this is to the disadvantage of the potential host plant. In one interesting case, a parasitic plant has evolved the ability to recognize the chemical signals produced by plants to attract beneficial fungi.

The holoparasite *Striga* (witchweed) is a serious pest of cereal crops in Africa. [Key Concept 35.4](#) described how arbuscular fungi are attracted to plant roots by compounds called strigolactones. One of these same molecules induces the seed germination of some parasitic plants, including *Striga*. Scientists strongly suspect that this is no coincidence. The mycorrhizal interaction is ancient (more than 400 million years old) and predates the evolution of parasitic plants. For this reason scientists hypothesize that a mechanism evolved in the ancestors of modern *Striga* to recognize a compound that was already produced by plants to attract soil microbes.

In *Striga* we thus find an example of "opportunistic evolution"—that is, the repurposing of preexisting processes rather than the development of new processes. This is not the first time you have encountered this phenomenon in this chapter. Recall that the formation of nodules by rhizobia uses some of the same mechanisms used by arbuscular fungi to establish residence inside plant cells (see [Figure 35.6](#)). This implies an evolutionary connection between the two symbioses.

35.5 recap

Carnivorous plants supplement their nutrition by extracting materials from animals. Rapid reflexes have evolved in some of these plants for trapping their prey. Parasitic plants, by contrast, get some or all of their sustenance from other plants. Holoparasites cannot function as auto-trophs, having lost chloroplast genes coding for photosynthetic machinery. At least one parasitic plant responds to the same signaling molecule that the host plant uses to attract beneficial fungi.

learning outcomes

You should be able to:

- Explain how carnivorous plants use nutrients from insects.
- Create a hypothesis to explain the evolution of a parasitic plant species.
- Analyze evidence that chemical signals involved in plant-bacteria and plant-fungi interactions represent an ancient process.

1. Describe the process by which carnivorous plants get nutrients from their prey. What is the primary nutrient they acquire?
2. Some mutant *Arabidopsis* plants that are very bushy (their shoots are more highly branched than wild-type plants) cannot make strigolactones because of a mutation in a gene necessary for strigolactone biosynthesis. If an investigator applies strigolactones to the plants, they grow normally. What does this experiment suggest about the role of strigolactones in plant growth? How does this add to the story of strigolactones as signals for arbuscules and parasitic plants?
3. Holoparasitic plants have lost many of the morphological and genetic traits necessary for an autotrophic lifestyle. From an evolutionary standpoint, how do you think this happened? (Hint: Think about selection pressures.)

investigatinglife

How can nitrogen use efficiency be improved?

We described in the opening of this chapter and in Investigating Life: Mycorrhizal Fungi Can Replace Fertilizer in Cassava Cultivation the possibility of improving plant nitrogen nutrition by manipulating the environment around the plant, in particular by adding fertilizers and mycorrhizae to the soil. Another approach is to improve the plant's ability to use this nutrient. Significant progress has been made in developing corn varieties with improved nitrogen use efficiency, using both conventional plant breeding (genetics) and biotechnology. The recent publication of the corn genome sequence will provide useful information about genes involved in nitrogen use. For example, the seed company Pioneer Hi-Bred is developing a strain of corn that produces a more efficient version of the enzyme glutamine synthetase (GS). GS adds ammonia to glutamate to form glutamine, and therefore plays an important role in nitrogen assimilation in plants. The new corn strain uses up to 20 percent less nitrogen fertilizer to produce the same yields as other corn varieties.

Future directions

As we pointed out at the beginning of the chapter, the manufacture of nitrogen fertilizer by the Haber-Bosch process is expensive, both in terms of energy needed and economic costs. For too many farmers, nitrogen deficiency limits the growth of their crops. At Yale University, a team of chemists led by Patrick Holland is attempting to design a new compound that binds nitrogen from the atmosphere, mimicking the natural process of nitrogen fixation. In nature, nitrogen fixation is catalyzed by the enzyme nitrogenase. Nitrogenase has iron and sulfur atoms where catalysis takes place. Holland's group has made simple molecules in which N and S are bound, but not too tightly, so that atmospheric N_2 binds the complex. Eventually the group hopes to develop a synthetic catalyst to make ammonia on-site at farms, replacing industrial ammonia-generating processes that require high temperatures and pressures.

► 35.1 Plants Require Nutrients

- Plants are photosynthetic autotrophs that can produce all their organic molecules from carbon dioxide, water, and minerals, including a nitrogen source.
- Mineral nutrients** are obtained from the **soil solution**.

mineral nutrients Inorganic ions required by organisms for normal growth and reproduction.

soil solution The aqueous portion of soil, from which plants take up dissolved mineral nutrients.

- Plants require 14 **essential elements**, 6 of which are **macronutrients** and 8 of which are **micronutrients**. **Deficiency symptoms** suggest what essential element(s) a plant lacks. Review [Figure 35.1](#), [Table 35.1](#), [Animation 35.1](#)

essential element A mineral nutrient required for normal growth and reproduction in plants and animals.

macronutrient In plants, a mineral element required in concentrations of at least 1 milligram per gram of plant dry matter; in animals, a mineral element required in large amounts. (Contrast with micronutrient.)

- The essential elements were discovered by growing plants **hydro-ponically**, with their roots suspended in mineral solutions instead of soil.

► 35.2 Plants Acquire Nutrients from the Soil

- Root growth allows plants, which are sessile, to search for mineral resources.
- Plants can regulate the uptake of nutrients by increasing the number or activity of active transport proteins in root epidermal cells. Review [Figure 35.2](#)

► 35.3 Soil Structure Affects Plant Nutrition

- Soils contain water, air, and inorganic and organic substances. Soils have living (biotic) and nonliving (abiotic) components. Review [Figure 35.3](#)
- A soil typically consists of two or three horizontal zones called **horizons**. **Topsoil** forms the uppermost or **A horizon**. Topsoil tends to lose mineral nutrients through **leaching**. **Loams** are excellent agricultural topsoils, with a good balance of sand, silt, clay, and organic matter. Review [Figure 35.4](#)

horizons The horizontal layers of a soil profile, including the topsoil (A horizon), subsoil (B horizon) and parent rock or bedrock (C horizon).

A horizon See topsoil.

leaching In soils, a process by which mineral nutrients in upper soil horizons are dissolved in water and carried to deeper horizons, where they are unavailable to plant roots.

loam A type of soil consisting of a mixture of sand, silt, clay, and organic matter. One of the best

soil types for agriculture.

- Soils form by mechanical and chemical [weathering](#) of rock. Chemical weathering imparts mineral nutrients to clay particles. Plant litter and other organic matter decompose to form [humus](#). Plants obtain some mineral nutrients through [cation exchange](#) between the soil solution and the surface of clay particles. **Review [Figure 35.5](#)**

weather The short-term state of atmospheric conditions (temperature, precipitation, humidity, wind direction and velocity) at a particular place and time. (Contrast with climate.)

humus (hew' mus) The partly decomposed remains of plants and animals on the surface of a soil.

cation exchange The process in soil by which cations bound to soil particles are released from the particles and made available to plant roots in soil water through the binding of hydrogen ions to the soil particles.

- Farmers use [fertilizers](#) to make up for deficiencies in soil mineral nutrient content.

fertilizer Any of a number of substances added to soil to improve the soil's capacity to support plant growth. May be organic or inorganic.

▶ 35.4 Soil Organisms Increase Nutrient Uptake by Plant Roots

- In the earliest stages of mycorrhiza formation, the hyphae of arbuscular fungi grow toward [strigolactones](#), compounds that are produced by the plant roots. **Review [Figure 35.6A](#)**

strigolactones Signaling molecules produced by plant roots that attract the hyphae of mycorrhizal fungi.

- Some [nitrogen fixers](#) live free in soil or water; others live symbiotically as [bacteroids](#) within plant roots. The formation of a [root nodule](#) requires interaction between the root system of a legume and rhizobia. **Review [Figure 35.6B](#)**

nitrogen fixers Organisms capable of fixing atmospheric N_2 to form NH_3 .

bacteroids Nitrogen-fixing organelles that develop from endosymbiotic bacteria.

root system The organ system that anchors a plant in place, absorbs water and dissolved minerals, and may store products of photosynthesis from the shoot system.

- Several steps in the formation of root nodules and arbuscules are similar and probably involve some of the same plant genes. **Review [Figure 35.7](#)**
- Mycorrhizae are symbiotic root-fungus associations that greatly increase a plant's absorption of water and minerals, especially phosphorus. They occur in more than 90 percent of terrestrial plant species. **Review [Investigating Life: Mycorrhizal Fungi Can Replace Fertilizer in Cassava Cultivation](#)**
- The arbuscules are the sites of nutrient exchange between the fungus and plant.
- In [nitrogen fixation](#), nitrogen gas (N_2) is reduced to ammonia (NH_3) or ammonium ions (NH_4^+) in a reaction catalyzed by **nitrogenase**. **Review [Figure 35.8](#), [Activity 35.1](#)**

nitrogen fixation Conversion of atmospheric nitrogen gas (N_2) into a more reactive and biologically useful form (ammonia), which makes nitrogen available to living things. Carried out by nitrogen fixers—bacteria, some of them free-living and others living within plant roots.

► 35.5 Carnivorous and Parasitic Plants Obtain Nutrients in Unique Ways

- **Carnivorous plants** are autotrophs that supplement a low nitrogen supply by feeding on insects or other small animals.
- **Parasitic plants** draw on other plants to meet their needs, which may include minerals, water, or the products of photosynthesis.

parasitic plants Plants that obtains some of their nutrition by growing on other plants.

- **Hemiparasites**, such as mistletoes, can still photosynthesize. **Holoparasites** cannot function as autotrophs because they have lost chloroplast genes that code for components of the photosynthetic apparatus (which they no longer need).

hemiparasite A parasitic plant that can photosynthesize, but derives water and mineral nutrients from the living body of another plant. (Contrast with holoparasite.)

holoparasite A fully parasitic plant (i.e., one that does not perform photosynthesis). (Contrast with hemiparasite.)

- A strigolactone—a compound in the same category of compounds plants use to attract mycorrhizal fungi—also induces the germination of some parasitic plants, including **Striga**. Scientists hypothesize that a mechanism evolved in the ancestors of modern **Striga** to recognize a compound that was already produced by plants to attract arbuscular fungi.

Review

- 5.1** Plants receiving insufficient quantities of essential elements can be evaluated by observing symptomatic changes in physical features and/or growth.
- 5.2** Experiments using hydroponic growth conditions have allowed scientists to determine the essential elements plants need for growth.

Original Paper: Brown, P. H., R. M. Welch and E. E. Cary. 1987. Nickel: A micronutrient essential for higher plants. *Plant Physiology* 85: 801-803.

Both barley and wheat are cereal crops used for feeding humans and livestock, and the two have many similarities. Because of its characteristics when fermented, however, barley is favored over wheat for beer making. When you consider how much beer is brewed around the world, it's no wonder that researchers have spent considerable effort looking for ways to optimize barley growth.

Optimizing growth of any crop can be accomplished if the crop's nutritional requirements are known. In the case of barley, one research group investigated the element nickel as a possible essential micro-nutrient. Earlier studies where a single generation of plants was grown without Ni indicated that it was not a mineral requirement. They began by creating a stock growth solution containing extremely low amounts of nickel ions (less than 30 nanograms per liter [ng/L]). Then they divided this stock solution into three containers and added nickel sulfate (NiSO_4) to two of these. This step produced supplemented concentrations of 0, 0.6, and 1.0 micromolar (μM) nickel sulfate in the three final solutions. These were then used as experimental growth solutions to grow three groups of barley plants over three generations under different nickel concentrations.

The researchers harvested seeds from third-generation plants in each group. They measured the total mass and number of seeds produced by each plant. Results are shown in the table below.

Plant group	Supplemented nickel concentration in growth solution (μM)	Total seed mass per plant (grams dry weight)	Total number of seeds harvested per plant
1	0	7.3	175
2	0.6	7.5	179
3	1.0	8.4	195

Next, one portion of the seeds from each group was analyzed for nickel content. The other portion from each group was placed in nickel-free growth medium and tested for germination. The graph below shows seed germination success plotted against nickel content of the same seeds.

Questions

1. The researchers concluded that nickel is an essential of barley. Do you agree with their conclusion? Explain your answer.
2. Analyze the data about the mass and number of seeds produced by the third-generation barley plants. What conclusion can you draw from these data? Is this consistent with your answer to Question 1 above? Explain.
3. Why didn't the researchers use soil to grow the barley plants? Will the experiments have to be repeated using soil as a growth medium, or can the results of this experiment be used to make predictions about plants grown in soil as well as in growth solutions?

A Nobel Prize for a Plant Biologist

In their constant search for ways to help farmers produce more food for a growing population, biologists have developed cereal crops whose physiology allows them to produce more grain per plant (resulting in higher yields). The drawback of this approach is that the sheer weight of the load of seeds may cause the stem to bend over. The problem is made worse when fertilizer added to the soil stimulates plants to grow taller. Harvesting seeds on the ground is very difficult; think of how hard it would be to pick up seeds one by one, when some have already sprouted.

In 1945 the U.S. Army temporarily occupied Japan, which was defeated in World War II. During the war, Japan, an island nation with a limited amount of land suitable for farming, was blockaded and could not import food or other supplies. Food was rationed and many people were hungry, but there were no major famines in Japan during that period. How were the Japanese able to produce enough grain to feed their population? The answer to this question lay in the fields: the Japanese had bred genetic strains of rice and wheat with short, strong stems, growing in thickness rather than height, that could bear high yields of grain without bending over. An agricultural advisor to the occupying American army sent samples of the grains to the United States.

A decade later, the American plant geneticist Norman Borlaug, who was working in Mexico at the time, began making genetic crosses between the Japanese wheat and other varieties that had genes conferring rapid growth, adaptability to varying climates, and resistance to fungal diseases. The results were “semi-dwarf” wheat varieties that gave record yields. The varieties were grown first in Mexico, and later in India and Pakistan during the 1960s. At about the same time and using a similar strategy, scientists in the Philippines developed semi-dwarf rice with equally spectacular results. People who had lived on the edge of starvation now produced enough food. Countries that had relied on food from other countries were now able to grow more than enough grain, and export the surplus. The development of these semi-dwarf grains began what was called the “Green Revolution.”⁰ Borlaug was awarded the Nobel Peace Prize for his research on wheat, which is estimated to have saved a billion lives.

QA How is plant growth controlled, and what changes in growth patterns made the new strains of wheat and rice successful?

36.1 Plants Develop in Response to the Environment

As you learned in [Chapter 33](#), plants can't move to get food and so must seek out resources above and below the ground. A number of unique features enable plants to obtain the resources they need to grow and reproduce:

Meristems. Plants have permanent collections of stem cells (undifferentiated, constantly dividing cells) that allow them to continue growing throughout their lifetimes.

Post-embryonic organ formation. Unlike animals, plants can initiate development of new organs such as leaves and flowers throughout their lifetimes.

Differential growth. Plants allocate resources to grow beneficial organs. For example, leaf growth allows plants to capture more sunlight or more roots permits greater water and nutrient uptake.

focus your learning

Plants use several mechanisms to maintain dormancy; these mechanisms must be overcome before a seed can germinate.

Seed germination begins with imbibition and ends with the emergence of the radicle, or embryonic root, in a process that requires plants to sense environmental changes.

Plants respond to environmental cues during growth by the use of signal transduction pathways involving hormones and photoreceptors.

Scientists use genetic screens to identify genes involved in the control of growth and development.

Plants must continuously monitor their ever-changing environments and redirect their growth appropriately. For example, the amount of available light changes from day to night and from season to season. In addition, other plants are often vying for the available light, and plants modulate their growth to compete with their neighbors for this precious resource. As you will see in this chapter, several mechanisms have evolved in plants that enable them to [*sense changes in their environments](#) and trigger appropriate growth responses.

Plant growth is regulated

The development of a plant—the series of progressive changes that take place throughout its life—is regulated in many ways. Key factors involved in regulating plant growth and development are:

Environmental cues, such as day length, water availability, and various chemicals in the environment

Receptors that allow a plant to sense environmental cues, such as photoreceptors that absorb light, and chemoreceptors that signal the presence of pathogens

Hormones—chemical signals that mediate the effects of the environmental cues, including those sensed by receptors

Regulatory proteins and enzymes that catalyze the biochemical reactions that control development

We will explore these ***regulatory mechanisms** in more detail later in this chapter. But first let's look at the initial steps of plant development—from seed to seedling—and the types of internal and external cues that guide them.

In early development, the seed germinates and forms a growing seedling

[Chapter 37](#) will describe the events of plant reproduction and development that lead to the formation of seeds. Here we begin with the seed, the structure that contains the early embryo. Unlike most animal embryos, plant seeds may be held in “suspended animation,” with the development of the embryo halted, for long periods. If development stops even when external conditions (such as water supply) are adequate for development, the seed is said to be **dormant**.

DORMANCY

Seed dormancy may last for weeks, months, or years. Plants use several mechanisms to maintain dormancy:

Exclusion of water or oxygen from the embryo by an impermeable seed coat

Mechanical restraint of the embryo by a tough seed coat

Chemical inhibition of germination by growth regulators

Photodormancy: some seeds need a period of light or dark before they can germinate

Thermodormancy: some seeds need high or low temperatures to germinate

Dormancy can be broken by conditions that overcome these mechanisms. For example, the seed coat may be damaged by passage through an animal's digestive system, or heavy rains may wash away chemical inhibitors. There are some unusual methods to overcome dormancy. One example is the breaking of dormancy by components of smoke. *Emmenanthe penduliflora* is a common plant in dry chaparral of the southwestern United States, an area that is prone to wildfires.

These plants germinate rapidly after a fire. John Keeley of Occidental College in Los Angeles found that dormancy in seeds of this plant is broken not by heat but by smoke—in particular, by the nitrogen oxides found in smoke. Other molecules in smoke have been identified that regulate seed germination.

Plant biologists distinguish between seed *dormancy*, which prevents germination under conditions that are suitable for plant growth, and seed *quiescence*, which occurs when a seed fails to germinate because conditions are unfavorable for growth. Some seeds may remain

quiescent, yet viable, for centuries; botanists have germinated a 1,300-year-old lotus seed recovered from a dry lake bed in China.

Seed dormancy and quiescence are common, so they must provide selective advantages for plants. Dormancy ensures that the seed will germinate at a time suitable for the plant to complete its life cycle. For example, some seeds require exposure to a long cold period (winter) before they germinate in the spring; this ensures that the plant has the entire growing season to mature and set new seeds. Dormancy and quiescence also help seeds survive droughts or long-distance dispersal, allowing plants to colonize new territory.

GERMINATION

Seeds begin to **germinate**, or sprout, when dormancy is broken and environmental conditions are satisfactory. The first step in germination is the uptake of water, called **imbibition** (from *imbibe*, “to drink in”). Before germination, a seed contains very little water: only 5-15 percent of its weight is water, compared with 80-95 percent in most other plant parts. Seeds also contain polar macromolecules, such as cellulose and starch, which attract and bind water molecules. Consequently a seed has a very negative water potential (see [Chapter 34](#)) and will take up water if the seed coat is permeable to water. The force exerted by imbibing seeds, which expand several-fold in volume, demonstrates the magnitude of their water potential; for example, imbibing cocklebur seeds can exert a pressure of up to 1,000 atmospheres.

imbibition Water uptake by a seed; first step in germination.

As a seed takes up water, it undergoes metabolic changes: enzymes are activated upon hydration, **RNA** and then proteins are synthesized, the rate of cellular respiration increases, and other metabolic pathways are activated. In many seeds, cell division is not initiated during the early stages of germination. Instead, growth results solely from the expansion of small, preformed cells.

As germination proceeds, starch, proteins, and lipids that are stored in the seed are hydrolyzed to provide metabolic energy and chemical building blocks—carbohydrates, amino acids, and lipid monomers—for the growing embryo. These reserves are stored in the **cotyledons** (the first leaf or leaves of the embryo) or in the endosperm (the non-embryonic storage tissue of the seed). Germination is completed when the **radicle** (embryonic root) emerges from the seed coat. The plant is then called a **seedling**.

cotyledon (kot' ul lee' dun) [Gk. *kotyledon*: hollow space] A “seed leaf.” An embryonic organ that stores and digests reserve materials; may expand when seed germinates.

radicle An embryonic root.

seedling A plant that has just completed the process of germination.

If the seed germinates underground, the new seedling must elongate rapidly (in the right direction!) and cope with a period of life in darkness or dim light. Photoreceptors that sense light and specialized cells that sense gravity direct this stage of development and prepare the seedling for growth in the light.

The pattern of early shoot development varies among the flowering plants. [Figure 36.1](#) shows the shoot development patterns of monocots and eudicots. In monocots, the growing shoot is protected by a sheath of cells called the **coleoptile** as it pushes its way through the soil. In eudicots, the shoot is protected by the cotyledons.

coleoptile A sheath that surrounds and protects the shoot apical meristem and young primary leaves of a grass seedling as they move through the soil.

(A) Monocot shoot development (corn)

(B) Eudicot shoot development (bean)

Figure 36.1 Patterns of Early Shoot Development (A) In grasses and some other monocots, growing shoots are protected by a coleoptile until they reach the soil surface. **(B)** In most eudicots, the growing point of the shoot is protected within the cotyledons.

Activity 36.1 Monocot Shoot Development www.Life11e.com/ac36.1

Activity 36.2 Eudicot Shoot Development www.Life11e.com/ac36.2

Several hormones and photoreceptors help regulate plant growth

The above description of the early stages of plant development illustrates some of the environmental cues that influence plant growth. A plant's responses to these cues involve signal transduction pathways. Various mechanisms are used by the plant to sense changes in the environment, and these mechanisms activate signal transduction pathways that result in the synthesis and activation of specific plant hormones. In turn, these hormones act as signals that trigger pathways resulting in changes in plant growth. In most cases these changes involve alterations in the expression of specific genes.

Hormones are chemical signals that act at very low concentrations at target sites often distant from where they are produced. Most plant hormones are very different from their counterparts in animals ([Table 36.1](#)). Each plant hormone plays multiple regulatory roles, and interactions among them can be complex. Several hormones regulate the growth and development of plants from seedling to adult ([Table 36.2](#)). Other hormones (for example, jasmonic acid and salicylic acid) are involved in the plant's defenses against herbivores and microorganisms, as we will discuss in [Chapter 38](#).

hormone (hore' mone) [Gk. *hormon*: to excite, stimulate] A chemical signal produced in minute amounts at one site in a multicellular organism and transported to another site where it acts on target cells.

table 36.1 Comparison of Plant and Animal Hormones

Characteristic	Plant hormones	Animal hormones
Size, chemistry	Peptides, small organic molecules	Peptides, proteins, small molecules
Site of synthesis	Usually at many locations	Specialized glands or cells
Site of action	Local or distant	Usually distant, transported
Effects	Often diverse	Often specific
Regulation	By biochemical feedback	By central nervous system, ions, or feedback

table 36.2 Plant Growth Hormones

Hormone	Structure	Typical activities
Absciscic acid*		Maintains seed dormancy; closes stomata
Auxins (mainly indole-3-acetic acid)		Promote stem elongation, adventitious root initiation, and fruit growth; inhibit axillary bud outgrowth, leaf abscission, and root elongation
Brassinosteroids		Promote stem and pollen tube elongation; promote vascular tissue differentiation
Cytokinins		Inhibit leaf senescence; promote cell division and axillary bud outgrowth; affect root growth
Ethylene		Promotes fruit ripening, leaf abscission, and senescence; inhibits stem elongation and gravitropism
Gibberellins (e.g., gibberellic acid)		Promote seed germination, stem growth, and ovule and fruit development; break winter dormancy; mobilize nutrient reserves in grass seeds

Perhaps the most important environmental cue for a plant is light: the source of energy for photosynthesis. Plants have an abundance of **photoreceptors** that detect changes in the quality and direction of light as well as the timing of light availability (day length). Photoreceptors are often proteins associated with pigments. Light acts directly on photoreceptors, which in turn regulate developmental processes that need to be responsive to light, such as the many changes that occur as a seedling emerges from the soil.

photoreceptors (1) In plants, pigments that trigger a physiological response when they absorb a photon. (2) In animals, the sensory receptor cells that sense and respond to light energy. (See cone cells, rod cells.)

Genetic screens have increased our understanding of plant signal transduction

In [Chapter 19](#) we described how genetic studies can be used to identify the steps along a developmental pathway. Recall the reasoning behind these experiments:

If a mutation in a specific gene disrupts a developmental process, then the product of that gene must be involved in that process.

In a similar way, genetic studies can be used to analyze pathways of receptor activation and signal transduction in plants:

If proper signaling does not occur in a mutant plant, then the mutant gene must be involved in the signal transduction process.

Mapping the mutant gene and identifying its function is a starting point for understanding the signaling pathway. *Arabidopsis thaliana* has been a major model organism for plant biologists investigating signal transduction.

One technique for identifying the genes involved in a plant signal transduction pathway is illustrated in [Figure 36.2](#). This technique, called a **genetic screen**, involves creating a large, random collection of mutant plants and identifying those individuals that are likely to have a defect in the pathway of interest. Plant genes can be randomly mutated in a variety of ways, including treatment with a chemical mutagen or the insertion of transposons (see [Key Concept 17.2](#)) randomly in the genome. After treatment, the plants are grown and then examined for a specific phenotype, usually a characteristic that is influenced by the pathway of interest. Once mutant plants have been selected, their genotypes are compared with those of wild-type plants. *Arabidopsis* mutants with altered developmental patterns have provided a wealth of new information about the mechanisms of hormone and receptor (particularly photoreceptor) action.

genetic screen A technique for identifying genes involved in a biological process of interest. Involves creating a large collection of randomly mutated organisms and identifying those individuals that are likely to have a defect in the pathway of interest. The mutated gene(s) in those individuals can then be isolated for further study.

research tools

1 A phenotype of interest is chosen, in this case response to ethylene. Growth of wild-type seedlings in the dark is altered by ethylene (right).

2 Seeds are treated with a mutagen and then planted.

Many seeds suspended in a mutagen solution in a test tube

3 The treated plants are grown in the dark and then screened. One mutant shows insensitivity to the hormone (uninhibited growth).

4 The gene involved in ethylene signaling is mapped, cloned, and studied.

Gene required for ethylene response

Figure 36.2 A Genetic Screen Genetics of the model plant *Arabidopsis thaliana* can be used to identify the steps of a signal transduction pathway. If a mutant strain does not respond to a hormone (in this case, ethylene), the corresponding wild-type gene must be essential for the pathway (in this case, ethylene response). This method has been instrumental to scientists in understanding plant growth regulation.

Q: In undertaking a search for natural mutant strains for ethylene response, how would you modify the procedure?

36.1 recap

Early embryonic development in many plants occurs within seeds, which may remain dormant for a long period. Water uptake (imbibition) and germination occur when external cues in the environment are present. As in animals, development in plants is under the control of signals and is mediated by hormones. These signals activate pathways that may result in changes in gene expression. Genetic screens have been useful in describing signal transduction pathways in the model plant *Arabidopsis thaliana*.

learning outcomes

You should be able to:

- Evaluate the importance of seed dormancy, and contrast it (in importance and process) with seed quiescence.
- List the ways a seed can maintain dormancy, and describe with examples how each method might be overcome to achieve germination.
- Explore the physical and metabolic changes a seed must undergo during the early stages of germination.
- Evaluate the importance of photoreceptors in plant development and growth, and compare the action of photoreceptors with that of hormones.
- Draw a simple diagram to illustrate how a genetic screen can be used to identify the genes involved in the development of plant signal transduction pathways.

-
1. Under what conditions would it be advantageous for a species to have seed dormancy broken by fire?
 2. What are the similarities and differences between hormone receptors and photoreceptors?
 3. How would a genetic screen be used to identify a plant gene involved in seed dormancy?

You have now seen the early stages of plant development and growth, and how the environment influences these processes. We will now turn to the subject of plant hormones, which are central to the internal regulation of development. We will describe how hormones were discovered and what physiological effects they have on plants. We will emphasize how genetic screens and other methods have led to a deeper molecular understanding of the action of plant hormones.

***connect the concepts** This chapter is devoted to how plants regulate their growth in response to environmental signals. [Chapter 38](#) is dedicated to how plants respond to environmental challenges such as pathogens, herbivory, and physical stresses.

***connect the concepts** Much of growth regulation occurs via signal transduction pathways. Review these mechanisms, mostly from animal cells, in [Chapter 7](#).

36.2 Gibberellins and Auxin Have Diverse Effects but a Similar Mechanism of Action

The discovery of two key plant hormones exemplifies the experimental approaches that plant biologists have used to investigate the mechanisms of plant development.

focus your learning

Gibberellins have multiple roles in plant growth and development.

The first discovered function of auxin related to its role in phototropism.

Polar transport of auxin distributes the hormone down the shoot; lateral transport distributes it from side to side.

Early in the twentieth century, two plant hormones were discovered: **gibberellins** (there are several active forms) and **auxin** (there are several forms, but one predominates). Initially, the discoveries came from observations of natural phenomena:

Gibberellins: In rice plants, a disease caused by the fungus *Gibberella fujikori* resulted in plants that grew overly tall and spindly.

Auxin: Biologists and indoor gardeners noted that seedlings would bend toward the light when placed near a light source.

gibberellin (jib er el' lin) A class of plant growth hormones playing roles in stem elongation, seed germination, flowering of certain plants, etc.

auxin (awk' sin) [Gk. *auxein*: to grow] In plants, a substance (the most common being indoleacetic acid) that regulates growth and various aspects of development.

A chemical substance was then isolated that could cause each phenomenon:

Gibberellic acid (see [Table 36.2](#)) made by the *G. fujikori* fungus caused rice plants to overgrow. Later it was found that plants make gibberellic acid as well, and that applying it to plants caused growth.

Indole-3-acetic acid (see [Table 36.2](#)) applied asymmetrically to the growing tips of seedlings caused cell elongation on the side away from the light, which resulted in the shoot bending toward the light.

Finally, mutant plants that do not make each hormone exhibit a phenotype expected in the absence of the hormone, and adding the hormone reverses that phenotype ([Figure 36.3](#)):

Tomato plants that do not make gibberellic acid are very short; supplying them with the hormone results in normal growth.

Arabidopsis thaliana individuals that do not make auxin are also short; supplying them with that hormone reverses that phenotype.

(A) Treatment with gibberellin

Twenty-two days after being sprayed with a dilute gibberellin solution, this plant reached the size of a nondwarf plant.

This untreated mutant plant did not make gibberellin and remained a dwarf.

(B) Treatment with auxin

Supplying auxin to this mutant plant made it grow.

This untreated mutant plant does not make auxin.

Figure 36.3 Hormones Reverse a Mutant Phenotype (A) The two mutant dwarf tomato plants in this photograph were the same size when the one on the right was treated with a gibberellin solution. (B) The short phenotype of this *Arabidopsis* mutant was reversed in the plant on the right by supplying auxin.

Note that the phenotype involved—short stature, or dwarfism—is similar in both mutant plants even though different hormones are involved. This observation exemplifies a concept that is

important to keep in mind when studying plant hormones: their *actions are not* unique and specific, as is the case with animal hormones (see [Table 36.1](#)).

The approaches outlined above—observation, hormone isolation, hormone treatment, and analysis of mutant plants—are just some of the methods used to identify plant hormones and understand their roles in plant development. Plant biologists have also studied hormones using chemical inhibitors and using plant transformation experiments that alter hormone levels or the plants' responses to hormones.

Gibberellins have many effects on plant growth and development

The functions of gibberellins can be inferred from the effects of experimentally decreasing gibberellins or blocking their action at various points in plant development. Such experiments reveal that gibberellins have multiple roles in regulating plant growth.

STEM ELONGATION

The effects of gibberellins on wild-type plants are not as dramatic as those seen on dwarf plants. However, gibberellins are indeed active in wild-type plants, because inhibitors of gibberellin synthesis cause a reduction in stem elongation. Such inhibitors can be put to practical uses. For example, plants such as chrysanthemums that are grown in greenhouses tend to get tall, but leggy plants do not appeal to consumers. Flower growers spray such plants with gibberellin synthesis inhibitors to control their height. Some wheat crops are similarly sprayed to keep them short, so they do not fall over when they produce grain; the result is chemically produced semi-dwarfs similar to the genetically produced varieties described in the opening story of this chapter. In some plants, such as cabbage, the normal growth habit is to be a squat, leafy head near the ground. When environmental signals are right, however, the plant “bolts,” quickly producing a tall stem with flowers—a response that can be mediated by gibberellins.

FRUIT GROWTH

Gibberellins and other hormones regulate the growth of fruits. Grapevines that produce seedless grapes develop smaller fruits than varieties that produce seed-bearing grapes. Biologists wanting to explain this phenomenon removed seeds from immature seeded grapes and found that this prevented normal fruit growth, suggesting that the seeds are sources of a growth regulator. Biochemical studies showed that developing seeds produce gibberellins, which diffuse into the immature fruit tissue. Spraying young seedless grapes with a gibberellin solution causes them to grow as large as seeded ones, and this is now a standard commercial practice ([Figure 36.4](#)).

Figure 36.4 Gibberellins and Fruit Growth Spraying developing seedless grapes with gibberellins (right) increases their size compared with untreated fruit (left).

MOBILIZATION OF SEED RESERVES

Early in seed germination, hydrolytic enzymes are produced to break down stored reserves of starch, proteins, and lipids. Just after imbibition in germinating seeds of barley and other cereals, the embryo secretes gibberellins. The hormones diffuse through the endosperm to a surrounding tissue called the **aleurone layer**, which lies underneath the seed coat. The gibberellins trigger a cascade of events in the aleurone layer, causing it to synthesize and secrete enzymes that hydrolyze proteins and starch stored in the endosperm (**Figure 36.5**). These observations have practical importance: in the beer brewing industry, gibberellins are used to enhance the “malting” (germination) of barley and the breakdown of its endosperm, producing sugar that is fermented to alcohol.

aleurone layer (al yu' rown) In some seeds, a tissue that lies beneath the seed coat and surrounds the endosperm. Secretes digestive enzymes that break down macromolecules stored in the endosperm.

Figure 36.5 Embryos Mobilize Their Reserves During seed germination in cereal grasses, gibberellins trigger a cascade of events that result in the conversion of starch and protein reserves into monomers that can be used by the developing embryo.

Q: In brewing beer, stored starch in barley seeds is converted to maltose. How do you think this is done in the brewery?

Activity 36.3 Events of Seed Germination www.Life11e.com/ac36.3

Another hormone, abscisic acid (ABA) (see [Table 36.2](#)) plays an antagonistic role with gibberellins in seed dormancy and germination. As we will describe in [Key Concept 37.1](#), ABA levels are high in dormant seeds and fall off during germination. Thus ABA plays a role in maintaining seed dormancy, whereas gibberellins function to break dormancy and promote germination.

Auxin plays a role in differential plant growth

Auxin was first discovered for its role in the bending of plants toward light. Subsequent research has shown that auxin is involved in many other aspects of plant growth and development.

IDENTIFYING AUXIN AND ITS TRANSPORT

Auxin (from the Latin “to increase”) was discovered in the context of **phototropism**: a response to light in which plant stems bend toward a light source. This was a familiar observation by biologists and home gardeners when the ever-curious Charles Darwin and his son Francis investigated this phenomenon and concluded that a signal was made in the shoot apex and diffused down the shoot in a polar (unidirectional)fashion, stimulating cell elongation.

phototropism [Gk. *photos*: light + *trope*: turning] A directed plant growth response to light.

Animation 36.1 Tropisms www.Life11e.com/a36.1

The Darwins worked with canarygrass (*Phalaris canariensis*) seedlings grown in the dark. While underground, a young grass seedling is protected by a coleoptile (see [Figure 36.1](#)). The coleoptiles of grasses are phototropic—they grow toward the light.

To find the light-receptive region of the coleoptile, the Darwins “blindfolded” the coleoptiles of dark-grown canarygrass seedlings in various places and then illuminated them from one side (**Investigating Life: The Darwins’ Phototropism Experiment**). The coleoptile grew toward the light whenever its tip was exposed. If the top millimeter or more of the coleoptile was covered, however, the coleoptile showed no phototropic response. The Darwins concluded that the tip contains the photoreceptor that responds to light. The actual bending toward the light, however, takes place in a growing region a few millimeters below the tip. Therefore, the Darwins reasoned, some *type of signal must travel from the tip of the coleoptile to the growing region*.

The Darwins’ Phototropism Experiment

The Darwins’ Phototropism Experiment

experiment

Original Paper: Darwin, C. R. assisted by F. Darwin. 1880. *The Power of Movement in Plants*. Chapter IX: Sensitiveness of plants to light: Its transmitted effects. London, John Murray.

Charles Darwin and his son Francis wanted to know how plants bend toward the light. They grew canarygrass seedlings (coleoptiles) in the dark. To discover what part of the coleoptile responds to light, they covered up ("blindfolded") different regions of each coleoptile and then exposed the seedlings to light from one side. The Darwins discovered that the tip of the seedling senses the light and that growth occurs below the tip. Their observations led them to hypothesize the existence of a growth-promoting signal produced by the coleoptile tip.

HYPOTHESIS ▶ Only part of the coleoptile senses the light that triggers phototropism.

METHOD

2 "Blindfold" the seedlings in different places and expose to light on one side.

RESULTS

3 Coleoptiles responded to light only when the tip was exposed.

CONCLUSION ▶ The coleoptile tip senses light and then transmits a growth signal to the tissue away from the light source.

work with the data

Fascinated by experiments showing that light induces plants to bend toward it and that this is due to increased growth on the "dark side" of the stem, Charles Darwin and his son Francis performed additional experiments on canarygrass (*Phalaris canariensis*) seedlings grown in the dark to learn more about how the seed germinates in the soil. Their conclusion that the light-sensing mechanism might reside in the coleoptile was validated when they repeated their experiments with the coleoptile tip cut off: bending did not occur. Because it was possible that the cut plants did not bend because they had been irreversibly damaged in some way, the Darwins repeated their initial experiment with undamaged seedlings whose coleoptile tips had been covered with a thin glass tube cap that was blacked out with India ink. In this case the plants did not bend. The Darwins' conclusion that the tip of the coleoptile senses the light and transmits a message to tissue below the tip to grow was initially controversial but ultimately led to the identification of auxin, the first plant growth hormone.

QUESTIONS

1. The figure shows a drawing by the Darwins of the bending of coleoptiles after 8 hours of light exposure. From which direction was the light shone?

Fig. 181.

2. The Darwins reported:

"Seven cotyledons [Note: The Darwins used the term "cotyledon" for what is now called a coleoptile.] had their tips cut off for lengths varying between 0.1 and 0.16 of an inch, and these, when left exposed all day to a lateral light, remained upright. In another set of 7 cotyledons, the tips were cut off for a length of only about 0.05 of an inch (1.27 mm) and these became bowed towards a lateral light, but not nearly so much as the many other seedlings in the same pots."

What do these data indicate about the possible role of the tip and about the possibility that injury in cutting blocks the bending response?

3. The Darwins described their further experiments:

"The summits of nine cotyledons, differing somewhat in height, were enclosed for rather less than half their lengths in uncoloured or transparent tubes; and these were then exposed before a south-west window on a bright day for 8 h. All of them became strongly curved towards the light, in the same degree as the many other free seedlings in the same pots; so that the glass-tubes certainly did not prevent the cotyledons from bending towards the light. Nineteen other cotyledons were, at the same time, similarly enclosed in tubes thickly painted with Indian ink. On five of them, the paint, to our surprise, contracted after exposure to the sunlight, and very narrow cracks were formed, through which a little light entered; and these five cases were rejected. Of the remaining 14 cotyledons, the lower halves of which had been fully exposed to the light for the whole time, 7 continued quite straight and upright; 1 was considerably bowed to the light, and 6 were slightly bowed, but with the exposed bases of most of them almost or quite straight."

What do these data indicate about the role of the tip? Can you explain why there was slight bending in six of the coleoptiles that were covered with painted tubes?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Others showed that placing the coleoptile tip (the source of the growth signal) on a decapitated coleoptile led to bending, even when a block of gelatin separated the tip and coleoptile.

In these experiments, the soluble growth signal moved from the coleoptile tip into the gelatin and then down into the decapitated coleoptile; later the growth signal was isolated from such gelatin blocks and identified as indole-3-acetic acid (see [Table 36.2](#)), the major form of auxin.

 Animation 36.2 **Went's Experiment** www.Life11e.com/a36.2

MECHANISM OF AUXIN TRANSPORT

The movement of auxin down a coleoptile is an example of polar (apical-to-basal) transport. Polar transport of auxin ([Figure 36.6](#)) depends on four biochemical processes that we hope you recognize from earlier chapters:

- *Diffusion across a cell membrane.* Polar molecules (in the chemical sense) diffuse across cell membranes less readily than nonpolar molecules (see [Key Concept 6.3](#)).
- *Membrane protein asymmetry.* Active transport carriers (see [Key Concept 6.4](#)) for auxin are located only in the portion of the cell membrane at the basal (bottom) end of the cell.
- *Proton pumping/chemiosmosis.* A proton pump (see [Figure 34.4](#)) moves H^+ from the cytoplasm to the cell wall, thereby increasing the intracellular pH and decreasing the pH in the cell wall. Proton pumping also sets up an electrochemical gradient (see [Key Concept 9.3](#)), which provides potential energy to drive the transport of auxin by the carriers mentioned above.
- *Ionization of a weak acid.* The main form of auxin, indole-3-acetic acid, is a weak acid (see [Key Concept 2.4](#)):

When the pH is low, this reaction is driven to the right, and HA (non-ionized auxin) is the predominant form. When the pH is higher, there is more A^- (ionized auxin).

Figure 36.6 Polar Transport of Auxin Proton pumps set up a chemiosmotic gradient directing ionized auxin (A⁻) toward the basally placed active transport carriers for auxin, which leads to a net movement of auxin in a basal direction.

While polar auxin transport distributes the hormone along the *longitudinal* (up and down) axis of the plant, *lateral* (side-to-side) redistribution of auxin is responsible for directional plant growth. This was shown in early experiments that followed the Darwins' when a coleoptile tip containing the growth hormone was placed asymmetrically on the decapitated coleoptile. The asymmetric distribution of growth hormone down the coleoptile resulted in excess growth on that side, and bending away from it, even in the absence of light:

The redistribution of auxin to one side is carried out by auxin carrier proteins that move from the base of the cell to one side; because of this, auxin exits the cell only on that side of the cell,

rather than at the base, and moves sideways within the tissue.

This lateral movement of auxin explains the bending of canarygrass seedlings toward light that the Darwins observed. When light strikes a canarygrass coleoptile on one side, auxin at the tip moves laterally toward the shaded side. The asymmetry thus established is maintained as polar transport moves auxin down the coleoptile, so that in the growing region below, the auxin concentration is highest on the shaded side. Cell elongation is thus stimulated on that side, causing the coleoptile to bend toward the light ([Figure 36.7A](#)).

Figure 36.7 Plants Respond to Light and Gravity Phototropism (A) and gravitropism (B) occur in shoot apices in response to a redistribution of auxin.

Light is not the only signal that can cause the redistribution of auxin. Auxin moves to the lower side of a shoot that has been tipped sideways, causing more rapid growth in the lower side and hence an upward bending of the shoot. Such growth in a direction determined by gravity is called **gravitropism** ([Figure 36.7B](#)). The upward gravitropic response of shoots is defined as negative gravitropism; that of roots, which bend downward, is positive gravitropism. Gravitropism in roots also involves differential growth caused by lateral movement of auxin, but the details of the mechanism differ between the root and the shoot.

gravitropism [L. *gravitas*: weight, force + Gk. *tropos*: to turn] A directed plant growth response to gravity.

Auxin affects plant growth in several ways

Like the gibberellins, auxin has many roles in plant development. Auxin affects the vegetative and reproductive growth of plants in several ways.

ROOT INITIATION

Cuttings from the shoots of some plants can produce roots and develop into entire new plants.

For this to occur, parenchyma cells in the interior of the shoot must dedifferentiate and form an apical meristem of a new root. These changes are similar to those that take place in the pericycle of a root when a lateral root forms (see [Figure 33.12](#)). Shoot cuttings of many species can be made to develop roots by dipping the cut surfaces into an auxin solution. These observations suggest that in an intact plant, the plant's own auxin plays a role in the initiation of lateral roots. Commercial preparations that enhance the rooting of plant cuttings typically contain synthetic auxins.

LEAF ABSCISSION

Auxin inhibits the detachment of old leaves from stems. This detachment process, called [abscission](#), is the cause of leaves falling from some trees in the autumn. Many leaves consist of a blade and a petiole that attaches the blade to the stem. Abscission results from the breakdown of a specific part of the petiole, the abscission zone ([Figure 36.8](#)). If the blade of a leaf is cut off, the petiole falls from the plant more rapidly than if the leaf had remained intact. If the cut surface is treated with an auxin solution, however, the petiole remains attached to the plant, often longer than an intact leaf would have. The timing of leaf abscission in nature appears to be determined in part by a decrease in the movement through the petiole of auxin produced in the blade.

abscission (ab sizh' un) [L. *abscissio*: break off] The process by which leaves, petals, and fruits separate from a plant.

Figure 36.8 Changes Occur When a Leaf Is about to Fall The breakdown of cells in the abscission zone of the petiole causes the leaf to fall.

APICAL DOMINANCE

Auxin helps maintain [apical dominance](#), a phenomenon in which apical buds inhibit the growth of axillary buds (see [Figure 33.1](#)), resulting in the growth of a single main stem with minimal branching. Apical dominance can be demonstrated by an experiment with a young seedling. If the plant remains intact, the stem elongates and the axillary buds remain inactive. Removal of the apical bud—the major site of auxin production—results in growth of the axillary buds. If the cut surface of the stem is treated with auxin, however, the axillary buds do not grow. The apical buds of branches also exert apical dominance: the axillary buds on the branch are inactive unless the apex of the branch is removed. That is why gardeners prune shrubs to encourage branching.

apical dominance In plants, inhibition by the apical bud of the growth of axillary buds.

FRUIT DEVELOPMENT

Fruit development normally depends on prior fertilization of the ovule (egg), but in many species treatment of an unfertilized ovary with auxin or gibberellins causes **parthenocarp**y—fruit formation without fertilization. Parthenocarpic fruits form spontaneously in some cultivated varieties of plants, including seedless grapes, bananas, and some cucumbers.

parthenocarpy Formation of fruit from a flower without fertilization.

CELL EXPANSION

Cell division followed by cell expansion is what causes plant growth. Because the plant cell wall normally prevents expansion of the cell contents inside the cell membrane (see [Key Concept 33.1](#)), the cell wall plays a key role in controlling the rate and direction of plant cell growth. Auxin acts on cell walls to regulate this process.

Cell expansion is driven mostly by the uptake of water, which enters the cytoplasm of the cell and accumulates in its central vacuole (see [Key Concept 33.1](#)). Growth of the vacuole accounts for most of the increase in volume of a growing cell, and the vacuole often makes up more than 90 percent of the volume of a mature cell. As the vacuole expands, it presses the cytoplasm against the cell wall, and the wall resists this force (the basis of turgor pressure). The cell wall is an extensively cross-linked network of polysaccharides and proteins, dominated by cellulose microfibrils. If the cell is to expand, some adjustments must be made in the wall structure to allow the wall to “give” under turgor pressure. Think of a balloon (the cell surrounded by a membrane) inside a box (the cell wall). How does the cell wall “box” loosen to allow expansion?

The **acid growth hypothesis** explains auxin-induced cell expansion (**Figure 36.9**). The hypothesis holds that protons (H^+) are pumped from the cytoplasm into the cell wall, lowering the pH of the wall and activating enzymes called expansins that catalyze changes in the cell wall structure, thereby causing the polysaccharides to adhere to each other less strongly. Expansins loosen the cell wall, making it easier to stretch as the cell expands. Auxin has two roles in this process: to increase the synthesis of the proton pumps, and to guide their insertion into the cell membrane. Auxin may also increase the activity of proton pump proteins already in the cell membrane by activating a protein kinase that phosphorylates the pump. Several lines of evidence support the acid growth hypothesis. For example, adding acid to the cell wall to lower the pH stimulates cell expansion even in the absence of auxin. Conversely, when a buffer is used to prevent the wall from becoming more acidic, auxin-induced cell expansion is blocked. The acid growth hypothesis applies to most species; in some plants, auxin stimulates secretion of new cell wall components quickly enough to account for even rapid changes in growth rate.

acid growth hypothesis The hypothesis that auxin increases proton pumping, thereby lowering the pH of the cell wall and activating enzymes that loosen polysaccharides. Proposed to explain auxin-induced cell expansion in plants.

Figure 36.9 Auxin Increases Cell Expansion The plant cell wall is an extensive network of cross-linked polymers. Auxin induces wall loosening by activating a proton pump that reduces pH in the cell wall.

Q: Where else in the plant cell are proton pumps important?

 Animation 36.3 Auxin Affects Cell Walls www.Life11e.com/a36.3

At the molecular level, auxin and gibberellins act similarly

The molecular mechanisms underlying both auxin and gibberellin action have been worked out with the help of genetic screens (see [Figure 36.2](#)). Biologists started by identifying mutant plants whose growth and development are insensitive to the hormones—that is, plants that are *not* affected by added hormone. Such mutant plants fall into two general categories:

- **Excessively tall plants.** These plants resemble wild-type plants given an excess of hormone and grow no taller when given extra hormone. They grow tall even when treated with inhibitors of hormone synthesis. Their hormone response is always “on,” even in the absence of the hormone. In such cases, it is presumed that the normal allele for the mutant gene codes for an inhibitor of the hormone signal transduction pathway. In wild-type plants, that pathway is “off,” but in the mutant plants, the pathway is “on” and the plant grows tall.
- **Dwarf plants.** These plants resemble dwarf plants that are deficient in hormone synthesis (see [Figure 36.3](#)), but they do not respond to added hormone. In these mutant plants the hormone response is always “off,” regardless of the presence of the hormone.

Remarkably, some mutations of both types turned out to affect *the same protein*, which turns out to be a repressor of a transcription factor that stimulates the expression of growth-promoting genes. The repressor protein has two important domains, which explains how mutations in the same protein can have seemingly opposite effects:

One region of the repressor protein binds to the transcription complex to inhibit transcription of growth-promoting genes. This is the region mutated in the excessively tall plants: the growth-promoting genes are always “on” because the repressor does not bind to the transcription complex.

Another region of the repressor protein causes it to be removed from the transcription complex. This is the region mutated in the dwarf plants: the growth-promoting genes are always “off”

because the repressor is always bound to the complex.

These observations allowed biologists to figure out how auxin and gibberellins work in wild-type plants. The repressor proteins involved in responding to the two hormones are different, but both hormones *act by removing the repressor from the *transcription complex* (**Focus: Key Figure 36.10**). The hormones do this by binding to a receptor protein, which in turn binds to the repressor. Binding of the hormone-receptor complex stimulates polyubiquitination of the repressor, targeting it for breakdown in the proteasome (see [Figure 16.20](#)). The receptors contain or associate with a region called an F-box that facilitates protein-protein interactions necessary for polyubiquitination of a target protein. Whereas animal genomes have few F-box-containing proteins, plant genomes have hundreds, an indication that this type of gene regulation is common in plants.

focus: key figure

Figure 36.10 Gibberellins and Auxin Have Similar Signal Transduction

Pathways Although the specific proteins involved are different, both hormones act to stimulate gene transcription by inactivating a repressor protein.

Q: Are the molecules (receptor, repressor, transcription factor, ubiquitin, proteasome) the same or different in auxin versus gibberellin signaling?

36.2 recap

Gibberellins are plant hormones that affect stem growth, fruit size, seed germination, and many other aspects of plant development; the effects vary from species to species. Auxin regulates cell expansion and thus mediates phototropism and gravitropism; it also plays roles in apical dominance, leaf abscission, fruit development, and root initiation. The acid growth hypothesis explains auxin-induced cell wall loosening. The molecular mechanisms by which gibberellins and auxin convey their effects on plants are similar: both hormones stimulate gene transcription by inactivating a repressor protein.

learning outcomes

You should be able to:

- Give evidence for the role of auxin in plant growth and development.
 - Give evidence for the role of gibberellins in various plant growth processes.
 - Compare polar and lateral transport of auxin, as they relate to the bending of shoots toward the light.
-
1. What would the result be, in terms of the synthesis of hydrolytic enzymes, if germinating barley seeds were treated with an inhibitor of mRNA translation? What would the result be if the seeds were treated with an inhibitor of proteasome function? What would be the result if the two inhibitors were applied to coleoptiles treated with auxin?
 2. Explain why, even though auxin moves away from the lighted side of a coleoptile tip, the coleoptile bends toward the light.
 3. Corn stunt spiroplasma (a bacterium) causes a significant reduction in the growth rate of infected corn plants. Diseased plants take on a dwarfed form. Since their appearance is reminiscent of a genetically dwarfed corn, you suspect that the bacterium may inhibit the synthesis of gibberellins by corn plants. Describe two experiments you might conduct to test this hypothesis, only one of which requires chemical measurement.

A corn plant infected with corn stunt spiroplasma

How can a single hormone, such as auxin or a gibberellin, have so many effects? As you have seen, a single signal transduction pathway may affect more than one gene. You will learn about other important plant hormones in the next section, and they too have multiple effects.

***connect the concepts** [Key Concept 16.2](#) explains how transcription factors bind to DNA and affect the rate of transcription in the regulation of gene expression.

36.3 Other Plant Hormones Have Diverse Effects

The discoveries of gibberellins and auxin led to the isolation of additional classes of plant hormones (see [Table 36.2](#)). These hormones have multiple effects, and they interact with one another in many cases.

focus your learning

Cytokinins are plant hormones that affect many plant growth functions related to cell division, growth, and senescence.

The gaseous hormone ethylene has several functions related to senescence, including fruit ripening; it also affects auxin gradients during shoot development.

Brassinosteroids, or plant steroid hormones, have a variety of functions that vary among plants.

Cytokinins are active from seed to senescence

Like bacteria and yeasts, plant cells such as parenchyma cells can be grown in a liquid or solidified growth medium containing sugars and salts. The cells will divide continuously until they run out of nutrients. In the early days of plant cell culturing, scientists experimented with many supplements to determine the optimal chemical environment for growth. The best supplement was coconut milk, the fluid that surrounds the developing embryo in coconut fruit. Investigators suspected that a molecule in the fluid must stimulate plant cell division.

A clue to the identity of the molecule came when Folke Skoog at the University of Wisconsin tested various pure substances that might substitute for coconut milk. DNA was among the substances tested, and it did not work; however, heating DNA at high pressure in an autoclave produced a mixture that strongly promoted plant cell division. A derivative of adenine called kinetin was identified as the active ingredient. Because it stimulated cell division (cytokinesis), it was called a [cytokinin](#).

cytokinin (sy' toe kine' in) A member of a class of plant growth substances that plays roles in senescence, cell division, and other phenomena.

Kinetin does not exist in cells, but it gave scientists a hint as to what type of molecule might be the active ingredient in coconut milk. An adenine derivative called [zeatin](#) was extracted from corn endosperm, and since then more than 150 different cytokinins have been isolated, and most are derivatives of adenine.

zeatin A cytokinin originally purified from corn kernels.

Cytokinins (see [Table 36.2](#)) have several different effects, in many cases interacting with auxin:

Adding an appropriate combination of auxin and cytokinins to a growth medium induces rapid

proliferation of cultured plant cells.

Cytokinins can cause certain light-requiring seeds to germinate even when kept in constant darkness.

In plant cell cultures, a high cytokinin-to-auxin ratio promotes the formation of shoots; a low ratio promotes the formation of roots.

Cytokinins usually inhibit the elongation of stems, but they cause lateral swelling of stems and roots (the fleshy roots of radishes are an extreme example).

Cytokinins stimulate axillary buds to grow into branches; the auxin-to-cytokinin ratio controls the extent of branching (bushiness) of a plant. A lower ratio promotes more branching.

Cytokinins delay the senescence of leaves. If leaf blades are detached from a plant and placed in water or a nutrient solution, they quickly turn yellow and show other signs of senescence. If instead they are placed in a solution containing a cytokinin, they remain green and senesce much more slowly. Roots contain abundant cytokinins, and cytokinin transport to the leaves delays senescence.

Ethylene is a gaseous hormone that hastens leaf senescence and fruit ripening

Whereas the cytokinins delay senescence, another plant hormone promotes it: the gas [ethylene](#) (see [Table 36.2](#)), which is sometimes called the senescence hormone. Ethylene can be produced by all parts of the plant, and like all plant hormones, it has several effects.

ethylene One of the plant growth hormones, the gas $\text{H}_2\text{C}=\text{CH}_2$. Involved in fruit ripening and other growth and developmental responses.

Back when streets were lit by gas rather than by electricity, leaves on trees near street lamps dropped earlier than those on trees farther from the lamps. We now know why: ethylene, a combustion product of the illuminating gas, caused the early abscission. Whereas auxin delays leaf abscission, ethylene strongly promotes it; thus the balance of auxin and ethylene controls abscission.

FRUIT RIPENING

By promoting senescence, ethylene also speeds the ripening of fruit. As a fruit ripens, it loses chlorophyll and its cell walls break down; ethylene promotes both of these processes. Ethylene also causes an increase in its own production. Thus once ripening begins, more and more ethylene forms, and because it is a gas, it diffuses readily throughout the fruit and even to neighboring fruits on the same or other plants. The old saying “one rotten apple spoils the barrel” is true. That rotten apple is a rich source of ethylene, which speeds the ripening and

subsequent rotting of the other fruit in a barrel or other confined space.

Farmers used to poke holes in developing figs to make them ripen faster. We now know that wounding causes an increase in ethylene production by the fruit, and that the raised ethylene level promotes ripening in many fruits, including apples, bananas, melons, apricots, and tomatoes. Today commercial shippers and storers of such fruit hasten ripening by adding ethylene to storage chambers. This use of ethylene is the single most important use of a natural plant hormone in agriculture and commerce.

Ripening can also be delayed by the use of “scrubbers” and adsorbents that remove ethylene from the atmosphere in fruit storage chambers.

As flowers senesce, their petals may abscise, decreasing their value in the cut-flower industry. Growers and florists often immerse the cut stems of ethylene-sensitive flowers in dilute solutions of silver thiosulfate before sale. Silver salts inhibit ethylene action by interacting directly with the ethylene receptor—thus they delay senescence, keeping flowers “fresh” for longer. An alternative product, used to delay fruit ripening and preserve cut flowers, is 1-methylcyclopropene, a gas that also binds to ethylene receptors and blocks their function.

STEM GROWTH

Although it is associated primarily with senescence, ethylene is active at other stages of plant development as well. Its effects on seedling development illustrate the interactions that occur among plant hormones. The hypocotyl of many eudicot seedlings forms an **apical hook** that protects the delicate shoot apex while the stem grows through the soil:

apical hook A form taken by the stems of many eudicot seedlings that protects the delicate shoot apex while the stem grows through the soil.

As in phototropic and gravitropic responses, the apical hook is maintained through an auxin

gradient, which promotes the elongation of cells on the outer surface of the hook. Once the seedling breaks through the soil surface and is exposed to light, the auxin level on the inside of the hook increases and the hook unfolds, raising the shoot apex and the expanding leaves into the sun.

There is evidence that ethylene controls the formation of the auxin gradient during seedling development. Treatment of darkgrown seedlings of some species with ethylene results in what is called the “triple response”: an exaggeration of the apical hook and a thickening and shortening of the hypocotyl and root (this response was exploited in a genetic screen for ethylene-response mutant plants; see [Figure 36.2](#)). It has been shown that ethylene affects both auxin synthesis and transport during apical hook development.

Brassinosteroids are plant steroid hormones

In animals, steroid hormones such as cortisol and estrogen are formed from cholesterol (see [Figure 40.2B](#)). Initially, biologists isolated a plant steroid hormone from the pollen of rape, a member of the Brassicaceae (mustard family). When applied to various plant tissues, this **brassinosteroid** (see [Table 36.2](#)) stimulated cell elongation, pollen tube elongation, and vascular tissue differentiation, but it inhibited root elongation. Since then, dozens of chemically related, growth-affecting brassinosteroids have been found in most plants.

Mutant plants that either do not make brassinosteroids or have defects in brassinosteroid reception and signal transduction are usually dwarf, infertile, and slow to develop. These effects can be reversed by adding small amounts of brassinosteroids, indicating that brassinosteroids are true hormones. These hormones have diverse effects, which vary among plants. Brassinosteroids can:

- promote xylem differentiation
- promote growth of pollen tubes during reproduction
- promote seed germination
- promote apical dominance and leaf senescence
- enhance cell elongation and cell division in shoots

The signaling pathway for these plant steroids differs sharply from those for steroid hormones in animals. In animals, steroids diffuse through the cell membrane and bind to receptors in the cytoplasm. In contrast, the receptor for brassinosteroids is an integral protein in the cell membrane.

36.3 recap

Cytokinins, ethylene, and brassinosteroids are hormones that work in concert with auxin and gibberellins to mediate plant development. They have various effects on different plants, ranging from stem growth to fruit ripening. They also interact in their effects with other hormones. Ethylene is remarkable in that it is a gas.

learning outcomes

You should be able to:

- Use information on the functions of cytokinins to predict how different aspects of plant growth will be affected by cytokinins and by various combinations of cytokinins and auxin.
- Describe the function of ethylene in fruit ripening, and explain its importance in the cut-flower and food-production industries.
- Identify some effects of brassinosteroids on plant growth.

-
1. A plant has an extremely bushy growth habit. What can you say about the likely auxin-to-cytokinin ratio in this plant?
 2. Supermarkets sell plastic bags that are impregnated with activated charcoal, which binds gases. The bags are designed to keep fruit fresh. How do they work?
 3. A plant shows rapid leaf senescence. Which hormone or hormones are most likely active in this plant? Which are most likely inactive?

A plant's response to light—the energy source for photosynthesis—is crucial to its survival. You saw how the Darwins' pioneering investigations of phototropism led to the discovery of auxin. Let's now look more closely at how plants sense and respond to light.

36.4 Photoreceptors Initiate Developmental Responses to Light

As we pointed out in [Key Concept 36.1](#), plants respond to many different environmental cues, and light is possibly the most important of these cues. Much has been learned about the receptors that plants use to sense light, and we will focus on those receptors here.

focus your learning

Plants have several blue-light receptor pigments.

Phytochrome, a photoreceptor pigment, controls plant responses to red and far-red light, and exists in two forms, P_r and P_{fr} .

What are plant photoreceptors?

Plants respond to two aspects of light: (1) its *quality*—that is, the wavelengths of light that can be absorbed by molecules in the plant; and (2) its *quantity*—that is, the intensity and duration of light exposure.

In [Chapter 10](#) you learned about the role of light in photosynthesis: how chlorophyll and other pigments absorb light at certain wavelengths (quality), and how light intensity affects photosynthetic rate (quantity). Here you'll learn how light affects plant development. Earlier in this chapter we described phototropism and how auxin mediates a plant stem's bending toward light. In addition to phototropism, light influences seed germination, shoot elongation, the initiation of flowering, and many other important aspects of plant development. Several photoreceptors take part in these processes. [Blue-light receptors](#) such as cryptochromes and phototropins mediate the effects of higher-intensity blue light, and phytochrome mediates the effects of red light.

blue-light receptors Pigments in plants that absorb blue light (400–500 nm). These pigments mediate many plant responses including photo-tropism, stomatal movements, and expression of some genes.

Phototropins, cryptochromes, and zeaxanthin are blue-light receptors

Charles and Francis Darwin showed that the apical tip of a growing coleoptile receives light as a signal and then redistributes auxin to stimulate cell elongation below the tip on the shaded side. You may recall from [Chapter 10](#) that an action spectrum involves exposing plants to different wavelengths of light to determine what wavelengths are most effective in driving a given process (e.g., photosynthesis). For photosynthesis, such studies showed that the most effective wavelengths are those absorbed by chlorophylls (see [Figure 10.4](#)). When an action spectrum was obtained for phototropism of coleoptiles, blue light (peak 436 nanometers [nm]) was found to be the most effective at inducing the coleoptile to curve ([Figure 36.11](#)). What is the blue-light-absorbing receptor/pigment? Biologists have used a genetic approach to answer this question, once again employing the model plant *Arabidopsis*.

(A) The absorption spectrum for phototropin

(B) Effect of blue light on coleoptiles

Figure 36.11 Action Spectrum for Phototropism (A) The action spectrum for bending of a coleoptile toward light is similar to the absorption spectrum for the receptor, phototropin. (B) After 90 minutes, only the coleoptiles exposed to blue light bend.

Researchers recovered blue-light-insensitive mutant *Arabidopsis* plants from a genetic screen and identified the gene for a blue-light receptor protein located in the cell membrane called **phototropin**. Phototropin protein has a flavin mononucleotide associated with it that absorbs blue light, leading to a change in the shape of the protein. This change exposes an active site for a protein kinase, which in turn initiates a signal transduction cascade that ultimately results in the stimulation of cell elongation by auxin. Phototropin is also involved in chloroplast movements in relation to light, and participates with another type of blue-light receptor, the plastid pigment **zeaxanthin**, in the light-induced opening of stomata.

phototropin Photoreceptor proteins that mediate light reception in plants.

zeaxanthin A blue-light receptor involved in the opening of plant stomata.

Another class of blue-light receptors is the **cryptochromes**, which absorb blue and ultraviolet light. These yellow pigments are located primarily in the plant cell nucleus and affect seedling development and flowering. The exact mechanism of cryptochrome action is not yet known. Strong blue light inhibits cell elongation through the action of cryptochromes, although the most rapid responses are mediated by phototropins.

cryptochromes [Gk. *kryptos*: hidden + *kroma*: color] Photoreceptors mediating some blue-light effects in plants and animals.

Phytochromes mediate the effects of red and far-red light

Photomorphogenesis refers to a number of physiological and developmental events in plants that are controlled by light. For example:

photomorphogenesis In plants, a process by which physiological and developmental events are controlled by light.

A bean seedling germinating below-ground has an elongated stem, a pale yellow, folded leaf, and a hook that protects the first leaves (see [Figure 36.1](#) and p. 778) — it is **etiolated**. As the seedling reaches the surface of the soil, it undergoes several light-induced changes: the apical hook straightens, the rudimentary leaves unfold, and chlorophyll is made, so that photosynthesis can begin. Even very dim light will induce these changes.

etiolated Process in flowering plants grown in the absence of light; characterized by long weak stems, smaller leaves due to longer internodes, and a pale yellow color.

Lettuce seeds spread on the soil will germinate only in response to light. Even just a flash of dim light will suffice.

Adult cocklebur plants flower when they are exposed to long nights. If there is a brief light flash in the middle of the night, they do not flower.

Action spectra of the above processes show that they are induced by red light (650-680 nm). This indicates that plants must have a photoreceptor pigment that absorbs red light and initiates photomorphogenesis.

What is especially remarkable about these red light responses is that *they are reversible by far-red light* (710-740 nm). For example, if lettuce seeds are exposed to brief, alternating periods of red and far-red light in close succession, they respond only to the final exposure. If it is red, they germinate; if it is far-red, they remain dormant ([Figure 36.12](#)). This reversibility of the effects of red and far-red light regulates many other aspects of plant development, including flowering and seedling growth.

Figure 36.12A Sensitivity of Seeds to Red and Far-Red Light

Original Paper: Borthwick, H. A., S. B. Hendricks, M. W. Parker, E. H. Toole and V. K. Toole. 1952. A reversible photoreaction controlling seed germination. *Proceedings of the National Academy of Sciences USA* 38: 662–666.

Lettuce seeds will germinate if exposed to a brief period of light. An action spectrum indicated that red light was most effective in promoting germination, but far-red light would reverse the stimulation if presented right after the red light flash. Harry Borthwick and his colleagues asked what would be the effect of repeated alternating flashes of red and far-red light. In each case, the final exposure determined the germination response. This observation led to the conclusion that a single, photoreversible molecule was involved. That molecule turned out to be phytochrome.

HYPOTHESIS▶ The effects of red and far-red light on lettuce seed germination are mutually reversible.

METHOD

Expose lettuce seeds to alternate periods of red light **R** for 1 minute and far-red light **FR** for 4 minutes.

CONCLUSION▶ Red light and far-red light reverse each other's effects.

work with the data

Figure 36.12B Sensitivity of Seeds to Red and Far-Red Light

Original Paper: Borthwick, H. A. et al. 1952.

Harry Borthwick, Sterling Hendricks, and colleagues at the U.S. Department of Agriculture performed a series of landmark experiments that suggested the existence of a receptor for red light that determined seed germination. Borthwick was the son of a leading plant pathologist who followed in his father's footsteps and studied plant physiology. After it was discovered that plants responded to the length of day (photoperiodism; see Chapter 37), the importance of nonphotosynthetic responses to light as a developmental signal became a hot topic of research. For over a century, it was known that lettuce seeds required light to germinate. By placing lettuce seeds in an environment where other environmental variables such as temperature were controlled, Borthwick's group tested the light signaling on germination.

QUESTIONS

- An action spectrum (see Figure 10.4) for seed germination was obtained by first soaking the seeds on wet filter paper in the dark for 16 hours for imbibition, and then exposing them to different wavelengths of light for 1 minute. Having been exposed to a possible germination signal, the seeds were returned to the dark and tested for germination after 2 days. The results are shown in **Table A** in terms of energy efficiency (how much light energy was required for 50% seed germination).
 - Explain the energy efficiency measurement: what do high and low numbers mean?
 - Plot the data as energy efficiency versus wavelength. What can you conclude about the most efficient wavelengths of light for germination?
- There was evidence from other light signaling responses in plants that the light effects were reversible by exposure to different wavelengths of light. After the data in **Table A** were obtained, Borthwick's team decided to first expose groups of 200 seeds to light at 660 nm (red, R)

for 1 minute, and then some batches to light at 700 nm (far-red, FR) for 4 minutes. The seeds were returned to the dark and germination evaluated after 2 days. **Table B** shows the results.

- What can you conclude about the nature of the light signal responder?
- Why was there some germination in the "None" condition?

Table A

Wavelength (nm)	Energy required for 50% seed germination
560	35
570	25
580	15
590	10
600	8
620	6
640	4
660	3
680	4
690	45
700	80

Table B

Wavelengths used	Percent germination
None	8.5
R	98
FR	54
R then FR then R	100
R then FR then R then FR	43
R then FR then R then FR then R	99

The basis for the effects of red and far-red light resides in the photoreceptor pigment protein in the cytoplasm of plants called **phytochrome**. Phytochrome exists in two interconvertible “iso-forms,” or states. The molecule undergoes a conformational change upon absorbing light at particular wavelengths. The default or “ground” state, which absorbs principally red light, is called **P_r**. When P_r absorbs a photon of red light it is converted into **P_{fr}**. P_{fr} is the active form of phytochrome—the form that triggers important biological processes in various plants.

phytochrome (fy' tow krome) [Gk. *phyton*: plant + *chroma*: color] A plant pigment regulating a large number of developmental and other phenomena in plants. It has two isomers: P_r, which absorbs red light, and P_{fr}, which absorbs far fr red light. P_{fr} is the active form.

P_r See phytochrome.

The part of phytochrome that absorbs red and far-red light is a covalently attached pigment called a chromophore (**Figure 36.13A**). The chromophore of P_r preferentially absorbs red light; when it does so, it changes conformation and the phytochrome is converted to the P_{fr} form. When the chromophore of P_{fr} absorbs far-red light, the phytochrome is converted back to the P_r form. If you know organic chemistry, this reaction is a familiar *cis-trans* isomerization.

(A) The *cis* and *trans* isomers of the chromophore pigment in phytochrome

(B) Absorbance spectra of P_r and P_{fr}

Figure 36.13 Phytochrome Exists in Two Forms Absorption spectra of

phytochrome reveal two interconvertible forms, corresponding to the *cis* and *trans* isomers of phytochrome's chromophore. The P_r form absorbs red light; the P_{fr} form absorbs far-red light.

The absorption spectra for P_r and P_{fr} correlate with their action spectra ([Figure 36.13B](#)). As you have seen, phytochrome affects seed germination, shoot development after etiolation, and flowering. In *Arabidopsis* there is a gene family that encodes five slightly different phytochromes, each functioning in different photomorphogenic responses.

For a plant in nature, the ratio of red to far-red light determines whether a phytochrome-mediated response will occur:

In daylight the ratio is about 1.2:1; because there is more red than far-red light, the P_{fr} form predominates.

In the shade of other plants, the ratio is as low as 0.13:1, and phytochrome is mostly in the P_r form. The low ratio of red to far-red light in the shade results from absorption of red light by chlorophyll in the leaves overhead, so less of the red light gets through to the plants below.

For some plants growing in the shade, the low ratio stimulates cell elongation and the plants grow upward toward the sun. The shade cast by other plants also prevents germination of seeds that require red light to germinate. The reflective properties of the soil can also affect the red to far-red ratio—and thus plant behavior. For example, cotton seedlings grow more slowly on soils (such as clay) that reflect more red than far-red light.

Phytochrome stimulates gene transcription

How does phytochrome, or more specifically P_{fr} , work? Phytochrome has two subunits ([Figure 36.14](#)), each composed of a protein chain and a chromophore. Gene transcription is stimulated when P_r is converted to the P_{fr} isoform. When P_r absorbs red light, the chromophore changes shape, causing change in the conformation of the protein itself, from the P_r form to the P_{fr} form. Conversion to the P_{fr} form exposes two important regions of the phytochrome protein, both of which affect transcriptional activity:

Exposure of a *nuclear localization sequence* (see [Figure 14.18](#)) results in movement of P_{fr} from the cytoplasm to the nucleus. Once in the nucleus, P_{fr} binds to transcription factors and thereby stimulates expression of genes involved in photomorphogenesis.

Exposure of a *protein kinase* domain causes P_{fr} protein to phosphorylate itself and other proteins involved in red-light signal transduction, resulting in changes in the activity of transcription factors.

Figure 36.14 Phytochrome Stimulates Gene Transcription Phytochrome is composed of two polypeptide chains, each with a chromophore. This pair of polypeptides undergoes a conformational change upon absorbing light. When phytochrome absorbs red light, it converts to the P_{fr} form, which activates transcription of phytochrome-responsive genes.

The effect of activating these transcription factors is quite large: in *Arabidopsis*, phytochrome affects an amazing 2,500 genes (10 percent of the entire genome!) by either increasing or decreasing their expression. Some of these genes are related to hormones. For example, when P_{fr} is formed in seed germination, genes for gibberellin synthesis are activated and genes for gibberellin breakdown are repressed. As a result, gibberellins accumulate and seed reserves are mobilized.

Circadian rhythms are entrained by light reception

The timing and duration of biological activities in living organisms are governed in all eukaryotes and some prokaryotes by what is commonly called a "biological clock"—an oscillator within cells that alternates back and forth between two states at roughly 12-hour intervals. The major outward manifestations of this clock are known as [circadian rhythms](#) (Latin *circa*, "about," + *dies*, "day"). Think of your own life: in all probability you sleep at night and are awake during the day. The circadian rhythms of animals are discussed in [Key Concept 52.5](#). In plants, circadian rhythms influence, for example, the opening (during the day) and closing (at night) of stomata in *Arabi-dopsis*, and the raising toward the sun (during the day) and lowering (at night) of leaves in bean plants. From these two examples, it is obvious that circadian rhythms are ecologically

useful adaptations, in that they relate the plant's physiology to its environment.

circadian rhythm (sir kade' ee an) [L. *circa*: approximately + *dies*: day] A rhythm of growth or activity that recurs about every 24 hours.

Two qualities characterize circadian rhythms, as well as other regular biological cycles: the **period** is the length of one cycle, and the **amplitude** is the magnitude of the change over the course of a cycle. The circadian rhythms of plants have several noteworthy characteristics:

period (1) A category in the geological time scale. (2) The duration of a single cycle in a cyclical event, such as a circadian rhythm.

amplitude The magnitude of change over the course of a regular cycle.

The period of a circadian rhythm is remarkably insensitive to temperature, although lowering the temperature may drastically reduce the amplitude.

Circadian rhythms are highly persistent; they may continue for days, even in the absence of environmental cues, such as light-dark periods.

Circadian rhythms can be entrained, within limits, by light-dark cycles that do not exactly correspond to 24 hours. That is, the period of a rhythm can be made to coincide (within limits) with that of the light-dark cycle to which the organism is exposed.

Consider what happens when a person abruptly moves across many time zones: what was the night becomes the day, and gradually the person's sleep-wakefulness circadian rhythm entrains to the new environmental cues. Similar entrainment occurs in plants adapting to day length as the seasons progress during the year. The action spectrum for plant entrainment indicates that phytochrome (and to a lesser extent, blue-light receptors) is very likely involved. At sundown phytochrome is mostly in the active P_{fr} form. But as the night progresses, P_{fr} gradually gets converted back to the inactive P_r form. By dawn phytochrome is mostly in the P_r state, but as daylight begins, it rapidly converts to P_{fr} . The switch to the P_{fr} state resets the plant's biological clock. However long the night, the clock is still reset at dawn every day. Thus while the total period measured by the clock is consistent, the clock adjusts to changes in day length over the course of the year.

36.4 recap

Light controls several physiological and developmental events in plants, a process called photomorphogenesis. Pigment photoreceptors such as phototropin, cryptochromes, and phytochrome mediate the effects of light on plant growth and development. Phytochrome exists in two interconvertible states; conversion from one state to the other is controlled by the ratio of red to far-red light. Circadian rhythms are influenced by light reception.

learning outcomes

You should be able to:

- Describe and evaluate evidence for the existence of blue-light receptors in plants.
- Explain the process and conditions under which conversion of the P_r and P_{fr} forms of phytochrome occur.

1. What is the evidence for blue-light receptors in plants?
2. Why does red light affect seed germination differently than far-red light does?

▶ investigatinglife

QA How is plant growth controlled, and what changes in growth patterns made the new strains of wheat and rice successful?

In normal wheat plants, gibberellins stimulate stem elongation. But in the semi-dwarf plants, a mutation affects the signal transduction mechanism for gibberellins so that the stem cells do not respond to it and growth is reduced. In rice, the mutation is in the gene for an enzyme in the biochemical pathway for the synthesis of gibberellins. Without the hormone, the stem does not elongate. The lives of countless people have been saved by intentional disruptions of hormone signaling. These high-yielding crops respond to added fertilizer with greatly increased growth and production of grain compared with conventional varieties of wheat and rice.

Future directions

Unlike animal hormones, which are made in one tissue and often have specific effects on a limited range of targets, plant hormones are widespread in their sites of synthesis and their effects. It is not surprising that with several hormones in a given tissue at a particular time, they interact to produce a physiological effect, a phenomenon called crosstalk. For example, as a seed germinates underground, the growth of the embryonic stem, or hypocotyl (see photo on p. 776, right column), is stimulated by auxin and gibberellins, and inhibited by ethylene and brassinosteroids. Studies on model plants such as *Arabidopsis* are revealing proteins common to the signaling pathways of these hormones that have a role in their interacting effects.

▶ Apply What You've Learned

Review

- 6.1 Plants respond to environmental cues during growth by the use of signal transduction pathways involving hormones and photoreceptors.
- 6.1 Scientists use genetic screens to identify genes involved in the control of growth and development.

Original Papers: Franklin, K. A., S. J. Davis, W. M. Stoddart, R. D. Vierstra and G. C. Whitelam. 2003. Mutant analyses define multiple roles for phytochrome C in *Arabidopsis* photomorphogenesis. *The Plant Cell* 15: 1981-1989.

Qin, M., R. Kuhn, S. Moran and P. H. Quail. 1997. Overexpressed phytochrome C has similar photosensory specificity to phytochrome B but a distinctive capacity to enhance primary leaf expansion. *The Plant Journal* 12: 1163-1172.

Sharrock, R. A. and T. Clack. 2002. Patterns of expression and normalized levels of the five *Arabidopsis* phytochromes. *Plant Physiology* 130:442-456.

Phytochromes sense red (R) and far-red (FR) light and control many processes in plant growth and development, including chlorophyll synthesis, seed germination, and leaf expansion. The phytochrome photoreceptor has two parts: a chromophore that receives light and a protein

involved in signal transduction for the response (see [Figure 36.14](#)). The model plant *Arabidopsis* has five distinct genes (*phyA*, *phyB*, *phyC*, *phyD*, and *phyE*) that control the formation of five types of phytochrome. These genes code for five slightly different proteins, the differential expression of which in different tissues at different times may underlie the varying responses of plants.

Elucidating the roles of the *phy* genes has involved both molecular and genetic approaches. In one molecular approach, a gene is coupled to a very active promoter and expressed at higher than normal levels (overexpressed) in developing *Arabidopsis* plants. For example, *phyA*, *phyB*, *phyC*, and *phyD* were separately overexpressed in *Arabidopsis*, and 18-day-old seedlings were examined with regard to leaf area. The table shows the results.

Gene expression	Leaf area (mm ²)
Wild type	22
<i>phyA</i> overexpressed	21
<i>phyB</i> overexpressed	21
<i>phyC</i> overexpressed	31
<i>phyD</i> overexpressed	22

To complement the molecular approach, a genetic approach—a genetic screen for plants expressing altered leaf size phenotypes—was used to isolate mutants deficient in *phyC* (see [Figure 36.2](#)). All of the *phyC* mutants found using the genetic screen turned out to also be genetically deficient in *phyD*. This result prompted an investigation of plants deficient in different combinations of *phy* genes. These plants were analyzed with regard to leaf length (which increases due to elongation of the petiole that connects leaf to stem) and leaf area. The results are shown in [Figures A](#) and [B](#).

Figure B

Questions

1. What do the data in the table indicate about the role of the four phytochrome genes in leaf development?
2. How would a genetic screen for *phyC*-deficient mutants be done, and what phenotype would be examined in the screen?
3. Compare the results for *phyAD*, *phyCD*, and *phyACD* in Figure B. What do these results tell you about the function and necessity of the *phyA* and *phyC* gene in controlling *Arabidopsis* leaf area?
1. What do the data in Figures A and B suggest about the function of the gene *phyB* in leaf growth? How does its function relate to the function(s) of *phyA* and *phyC*?

▶ 36.1 Plants Develop in Response to the Environment

- As sessile organisms, plants maximize their ability to grow by using meristems, forming new organs, and growing throughout life.
- The environment, receptors, hormones, and the plant's genome all regulate plant development.
- Seed **dormancy**, which has adaptive advantages, is maintained by a variety of mechanisms. In nature, dormancy is broken by, for example, abrasion, fire, leaching, and low temperatures. When dormancy ends and the seed **imbibes** water, it **germinates** and develops into a **seedling**. **Review Figure 36.1, Activities 36.1,36.2**

dormancy A condition in which normal activity is suspended, as in some spores, seeds, and buds.

seedling A plant that has just completed the process of germination.

- Plant hormones differ in structure and physiology from animal hormones. **Review Table 36.1**
- Plants have several hormones, each of which regulates multiple aspects of development. Interactions among these hormones are often complex. **Review Table 36.2**
- **Genetic screens** using the model organism *Arabidopsis thaliana* have contributed greatly to our understanding of signaling in plants. **Review Figure 36.2**

genetic screen A technique for identifying genes involved in a biological process of interest. Involves creating a large collection of randomly mutated organisms and identifying those individuals that are likely to have a defect in the pathway of interest. The mutated gene(s) in those individuals can then be isolated for further study.

▶ 36.2 Gibberellins and Auxin Have Diverse Effects but a Similar Mechanism of Action

- Both **gibberellins** and **auxin** can induce growth in plants otherwise genetically destined to be dwarfs. **Review Figure 36.3**

gibberellin (jib er el' lin) A class of plant growth hormones playing roles in stem elongation, seed germination, flowering of certain plants, etc.

auxin (awk' sin) [Gk. *auxein*: to grow] In plants, a substance (the most common being indoleacetic acid) that regulates growth and various aspects of development.

- Gibberellins have many effects that vary among different plants, including cell elongation, fruit ripening, and mobilization of seed storage polymers. **Review Figures 36.3-36.5, Activity 36.3**

- Auxin was discovered in the context of stem and coleoptile growth, in particular [phototropism](#). In the shoot, it is made in the growing tip and transported down to stimulate cell elongation. **Review Investigating Life: The Darwins' Phototropism Experiment**, [Figures 36.6, 36.7](#), [Animations 36.1, 36.2](#)

phototropism [Gk. *photos*: light + *tropē*: turning] A directed plant growth response to light.

- According to the [acid growth hypothesis](#), auxin stimulates cell elongation through the release of protons into the cell wall (acidification of the cell wall). **Review Figure 36.9**, [Animation 36.3](#)

acid growth hypothesis The hypothesis that auxin increases proton pumping, thereby lowering the pH of the cell wall and activating enzymes that loosen polysaccharides. Proposed to explain auxin-induced cell expansion in plants.

- Both auxin and gibberellins act through the breakdown of transcriptional repressors. **Review Focus: Key Figure 36.10**

▶ 36.3 Other Plant Hormones Have Diverse Effects

- Cytokinins are adenine derivatives that promote plant cell division, promote seed germination in some species, inhibit stem elongation, promote lateral swelling of stems and roots, stimulate the growth of axillary buds, promote the expansion of leaf tissue, and delay leaf senescence.
- A balance between auxin and [ethylene](#) controls leaf abscission. Ethylene promotes senescence and fruit ripening. It indirectly causes the formation of a protective [apical hook](#) in eudicot seedlings. In stems, it inhibits elongation, promotes lateral swelling, and causes a loss of gravitropic sensitivity.

ethylene One of the plant growth hormones, the gas $\text{H}_2\text{C}=\text{CH}_2$. Involved in fruit ripening and other growth and developmental responses.

apical hook A form taken by the stems of many eudicot seedlings that protects the delicate shoot apex while the stem grows through the soil.

- Dozens of different [brassinosteroids](#) affect cell elongation, pollen tube elongation, vascular tissue differentiation, and root elongation.

brassinosteroids Plant steroid hormones that mediate light effects promoting the elongation of stems and pollen tubes.

▶ 36.4 Photoreceptors Initiate Developmental Responses to Light

- Phototropins are blue-light photoreceptors for phototropism and chloroplast movements. [Zeaxanthin](#) acts in conjunction with the phototropins to mediate the light-induced opening of stomata. [Cryptochromes](#) are blue-light photoreceptors that control seedling development, stem elongation, and floral initiation.

zeaxanthin A blue-light receptor involved in the opening of plant stomata.

cryptochromes [Gk. *kryptos*: hidden + *kroma*: color] Photoreceptors mediating some blue-light effects in plants and animals.

- Phytochrome exists in the cytoplasm in two interconvertible forms, **P_r** and **P_{fr}**. The relative amounts of these two forms are a function of the ratio of red to far-red light. Phytochrome affects seedling growth, flowering, and etiolation. **Review** [Figures 36.12, 36.13](#)

P_{fr} See phytochrome.

- The phytochrome signal transduction pathway affects transcription in two different ways; the P_{fr} form interacts directly with some transcription factors, and influences transcription indirectly through interactions with protein kinases. **Review** [Figure 36.14](#)
- Circadian rhythms are activities that occur on a near-24-hour cycle. Light can entrain these activities through photoreceptors such as phytochrome.

Reproduction in Flowering Plants

The poinsettia is a popular Christmas flower. But the red "flowers" are not flowers at all; instead, they are leaves (bracts).

key concepts

[7.1 Most Angiosperms Reproduce Sexually](#)

[7.2 Hormones and Signaling Determine the Transition from the Vegetative to the Reproductive State](#)

investigatinglife

What Signals Flowering?

Dairy farmer Albert Ecke was fascinated by the red and green shrubs that grew all over southern California and were used by Mexican-Americans for red dye. The shrub, *Euphorbia pulcher-rima*, got the name "poinsettia" from the man who first brought it to the United States: the first U.S. ambassador to Mexico, Joel Roberts Poinsett. In the early 1900s, Ecke started selling the plants at his farm in Hollywood. But two challenges stood in the way of his making this plant a commercial success.

First, although poinsettias generally bloomed in the fall and early winter in the mild climate of southern California, when Ecke grew them in fields in Hollywood, the formation of flowers was unreliable. Biologists later found that the flowering of poinsettias required at least a 14-hour night for several weeks. Any interruption in the long night—by passing cars or street lamps or lighting from nearby movie sets, for example—inhibited flowering. So Ecke's son Paul moved the growing operation south, to isolated fields far from Los Angeles. A second challenge was that the plants were tall and gangly. Although pretty, they were hard to transport and not attractive indoors. Paul Ecke found a variety of poinsettia that was much more compact. He propagated this variety and eventually developed it into the short potted plant that is so popular today. The Eckes decided that the time of flowering was just right for making the poinsettia a "Christmas flower," so they promoted this now portable plant as a holiday decoration, blanketing live television shows with free plants between Thanksgiving and Christmas. The campaign was successful: more than 100 million poinsettias are now sold in the United States during the Christmas season every year, making it the nation's best-selling potted plant.

Breeding more attractive flowering plants that are easier to grow is an ongoing part of floriculture, the industry involved with the production of floral crops. You may be surprised to learn that the brightly colored "flowers" of poinsettias are not flowers at all. The red parts of the plant that we most notice and appreciate are actually specialized leaves called bracts. The poinsettia has a single tiny yellow female flower, without petals, surrounded by male flowers.

QA How did an understanding of angiosperm reproduction allow floriculturists to develop a commercially successful poinsettia?

37.1 Most Angiosperms Reproduce Sexually

Most angiosperms (flowering plants) have evolved to reproduce sexually because this strategy has the selective advantage of producing the genetic diversity that is the raw material for evolution. Sexual reproduction in angiosperms involves mitosis, meiosis, and the alternation of haploid and diploid generations (see [Figure 11.14](#)).

focus your learning

The embryo sac is the female gametophyte and the pollen grain is the male gametophyte.

A pollen grain germinates to form a pollen tube, which grows through the style to the embryo sac.

Angiosperms prevent self-fertilization by physically separating male and female gametophytes and by genetic self-incompatibility.

The embryo and endosperm develop within the seed, enclosed within a fruit derived from the ovary wall.

There are several important differences between sexual reproduction in angiosperms and in vertebrate animals:

In most angiosperms, there are multicellular diploid (sporophyte) and haploid (gametophyte) life stages (alternation of generations); in animals, there is no multicellular haploid stage.

In angiosperms, the cells that will form gametes are determined in the adult organism, usually in response to environmental conditions; in animals, the germ line cells are determined before birth.

Meiosis in plants produces spores, after which mitosis produces gametes; in animals, meiosis usually produces gametes directly.

How does the flower function as a structure for sexual reproduction?

The plant life cycle typically involves the alternation of haploid and diploid generations (see [Key Concept 11.4](#)):

In angiosperms, the adult plant is a diploid sporophyte, and the male and/or female haploid gametophytes (structures that produce gametes) are contained in the flowers (see [Key Concept 28.1](#) for a description of flower parts and floral evolution). A complete flower consists of four concentric groups of organs arising from modified leaves: the carpels, stamens, petals, and sepals.

The carpels are the female sex organs that contain the developing female gametophytes.

The stamens are the male sex organs that contain the developing male gametophytes.

You learned in [Chapter 19](#) how specific transcription factors control the differentiation of the meristem into the various organs of the flower. Most angiosperms have flowers with both stamens and carpels; such flowers are termed "perfect" ([Figure 37.1A](#)). "Imperfect" flowers, by contrast, are those with only male or only female sex organs. Male flowers have stamens but not carpels, and female flowers have carpels but not stamens. Some plants, such as corn, bear both male and female flowers on an individual plant; such species are called [monoecious](#) ("one house") ([Figure 37.1B](#)). In **dioecious** species, individual plants bear either male-only or female-only flowers; an example is holly ([Figure 37.1C](#)).

monoecious (mo nee' shus) [Gk. *mono*: one + *oikos*: house] Pertaining to organisms in which both sexes are "housed" in a single individual that produces both eggs and sperm. (In some plants, these are found in different flowers within the same plant.) Examples include corn, peas, earthworms, hydras. (Contrast with dioecious.)

(A) Perfect: lily (*Lilium* sp.)

(B) Imperfect monoecious: corn

**(C) Imperfect dioecious:
American holly (*Ilex opaca*)**

Figure 37.1 Perfect and Imperfect Flowers (A) A lily is an example of a perfect flower, meaning one that has both male and female sex organs. (B) Imperfect flowers are either male or female. Corn is a monoecious species: both types of imperfect flowers are borne on the same plant. (C) American holly is a dioecious species; some American holly plants bear male imperfect flowers whereas others bear female imperfect flowers.

Flowering plants have microscopic gametophytes

You can follow the roles of male and female gametophytes in an-giosperm reproduction in [Figure 37.2](#). The gametophytes develop from haploid spores in the flower:

Figure 37.2 Sexual Reproduction in Angiosperms The embryo sac is the female gametophyte; the pollen grain is the male gametophyte. The male and female cells meet and fuse within the embryo sac. Angiosperms have double fertilization, in which a zygote and an endosperm form from separate fusion events. The zygote forms by the fusion of one sperm cell with the egg cell. The endosperm forms after the other sperm cell fuses with the central cell, which contains two nuclei. The three nuclei fuse, forming a triploid cell.

Activity 37.1 Sexual Reproduction in Angiosperms www.Life11e.com/ac37.1

Each female gametophyte (megagametophyte) is called an **embryo sac**, and it develops inside an ovule. One or more ovules are contained within the ovary, which is the lower part of the carpel.

embryo sac In angiosperms, the female gametophyte. Found within the ovule, it consists of eight or fewer cells, membrane bounded, but without cellulose walls between them.

Male gametophytes (microgametophytes), which are called **pollen grains**, develop inside the anther, which is part of the stamen.

pollen grain [L. *pollin*: fine flour] In seed plants, microscopic grains that contain the male gametophyte (microgametophyte) and gamete (microspore).

FEMALE GAMETOPHYTE

Of the four haploid megaspores resulting from meiosis, three undergo apoptosis (programmed cell death). The remaining megaspore undergoes three mitotic divisions without cytokinesis, producing eight haploid nuclei, all initially contained within a single cell—three nuclei at one end, three at the other, and two in the middle. Subsequent cell wall formation leads to an elliptical, seven-celled megagametophyte with a total of eight nuclei:

At one end of the megagametophyte are three small cells: the egg cell and two cells called synergids. The egg cell is the female gamete, and the synergids participate in fertilization by attracting the pollen tube. The pollen tube enters one of the synergids before the sperm cells are released for fertilization.

At the opposite end of the megagametophyte are three antipodal cells, which eventually degenerate.

In the large central cell are two [polar nuclei](#).

polar nuclei In angiosperms, the two nuclei in the central cell of the megagametophyte; following fertilization they give rise to the endosperm.

The megagametophyte, or embryo sac, is the entire seven-cell, eight-nucleus structure.

MALE GAMETOPHYTE

The four haploid products of meiosis (the microspores) each develop a cell wall and undergo a single mitotic division, usually producing four two-celled pollen grains that are released into the environment. The two cells in a pollen grain have different roles:

After pollination (see below) the generative cell divides by mitosis to form two sperm cells that participate in fertilization.

The tube cell forms the elongating pollen tube that delivers the sperm to the embryo sac.

These events occur after the pollen grain is transferred to a stigma (part of the female reproductive organ)—a process called [*pollination](#).

A pollen tube delivers sperm cells to the embryo sac

When a functional pollen grain lands on the stigma of a compatible stigma, it germinates. A key event is water uptake by pollen from the stigma: pollen loses most of its water as it matures. Germination involves the development of a [pollen tube](#) ([Figure 37.3](#)). The pollen tube either traverses the tissue of the style (part of the carpel; see [Figure 37.2](#)) or, if the style is hollow, grows on the inner surface of the style until it reaches an ovule. The growth rate of the pollen tube varies greatly among species, but it can be as fast as 1 centimeter an hour.

pollen tube A structure that develops from a pollen grain through which sperm are released into the megagametophyte.

Figure 37.3 Pollen Tubes Begin to Grow Staining pollen with a dye allows it to be seen through a microscope. These pollen grains have landed on the stigmas of a crocus.

Q: How do you think the pollen tube grows in length? What processes are involved in the pollen tube descending the solid tissue of the style?

Media Clip 37.1 **Pollen Germination in Real Time** www.Life11e.com/mc37.1.

The growth of the pollen tube is guided in part by a chemical signal in the form of a small protein produced by the synergids within the ovule. If one synergid is destroyed, the ovule still attracts pollen tubes, but destruction of both synergids renders the ovule unable to attract pollen tubes, and fertilization does not occur.

Genetic screens (see [Figure 36.2](#)) of mutants in *Arabidopsis* have revealed several genes whose expression in synergids is needed for guiding the pollen tube. There is evidence that a small molecule made by the embryo sac— γ -aminobutyric acid, or GABA—is an attractant for pollen tube growth. This would be an amazing coincidence, since this molecule is also a signal in the vertebrate nervous system.

Many flowering plants control pollination or pollen tube growth to prevent inbreeding

You'll recall from discussions of Mendel's work (see [Key Concept 12.1](#)) that some plants can reproduce sexually by both cross-pollination and self-pollination. Self-pollination increases the chances of successful pollination but leads to homozygosity, which reduces genetic diversity. Because diversity is the raw material of evolution by natural selection, homozygosity can be selectively disadvantageous. Most plants have evolved mechanisms that prevent ***self-fertilization**. Angiosperms prevent self-fertilization in two main ways: (1) physical separation of male and female gametophytes and (2) genetic self-incompatibility.

SEPARATION OF MALE AND FEMALE GAMETOPHYTES

Self-fertilization is prevented in dioecious species, which bear only male or female flowers on a particular plant. Pollination in dioecious species is accomplished only when one plant pollinates another. In monoecious plants, which bear both male and female flowers on the same plant, the physical separation of the male and female flowers is often sufficient to prevent self-fertilization. Some monoecious species prevent self-fertilization by staggering the development of male and female flowers so they do not bloom at the same time, making these species functionally

dioecious.

GENETIC SELF-INCOMPATIBILITY

A pollen grain that lands on the stigma of the same plant will fertilize the female gamete *only if the plant is self-compatible*, meaning capable of self-pollination. To prevent self-fertilization, many plants are genetically self-incompatible. **Self-incompatibility** depends on the ability of a plant to determine whether pollen is genetically similar or genetically different from itself. Rejection of "same-as-self" pollen prevents self-fertilization. How does it occur?

Self-incompatibility in many flowering plants is controlled by a cluster of tightly linked genes called the S locus (for self-incompatibility). The S locus encodes proteins in the pollen and style that interact during the recognition process. A self-incompatible species typically has many alleles of the S locus. The pollen phenotype may be determined by its own haploid genotype or by the diploid genotype of its parent plant. In either case, if the pollen expresses an allele that matches either of the alleles expressed in the recipient pistil, the pollen is rejected. Depending on the type of self-incompatibility system, the rejected pollen either fails to germinate or is prevented from growing through the style (Figure 37.4); either way, self-fertilization is prevented.

Figure 37.4 Self-Incompatibility In a self-incompatible plant, pollen is rejected if it expresses an S allele that matches one of the S alleles of the stigma and style. Self pollen may (A) fail to germinate or (B) its pollen tube may die before reaching an ovule. In either case, the egg cannot be fertilized by a sperm from the same plant.

Angiosperms perform double fertilization

In most angiosperm species, the mature pollen grain consists of two cells: a large tube cell enclosing a much smaller generative cell. When a compatible pollen grain lands on the stigma of a plant of the same species, it germinates, and the pollen tube grows through the style tissue to the embryo sac. During this process, the generative cell undergoes one mitotic division and cytokinesis to produce two haploid **sperm cells** (Figure 37.5, steps 1 and 2).

sperm cells See sperm.

Figure 37.5 Double Fertilization Two sperm are involved in two cell fusion events, hence the term "double fertilization." One sperm is involved in the formation of the diploid zygote, and the other results in the formation of the triploid endosperm cell that divides to form endosperm. Double fertilization is a characteristic feature of angiosperm reproduction.

Animation 37.1 **Double Fertilization** www.Life11e.com/a37.1

Two fertilization events now occur. One of the two synergids degenerates when the pollen tube arrives and the two sperm cells are released into its remains ([Figure 37.5, step 3](#)). Each sperm cell then fuses with a different cell of the embryo sac ([Figure 37.5, steps 4 and 5](#)). One sperm cell fuses with the egg cell, and the two nuclei fuse, producing the diploid zygote. The other sperm cell fuses with the central cell, and its nucleus fuses with the two polar nuclei, forming a **triploid ($3n$) cell**. Immediately after fertilization the triploid nucleus undergoes rapid mitotic divisions to form a specialized nutritive tissue, the **endosperm**. In most species the endosperm nucleus initially divides without cytokinesis, forming a large, multi-nucleate cell, and cell walls form later between the nuclei. After the endosperm begins developing, the zygote undergoes mitotic division to form the new sporophyte embryo. The developing embryo uses the endosperm tissue as a source of nutrients, energy, and carbon-based anabolic building blocks. In some cases the endosperm persists until germination and is used as a source of nutrients by the developing seedling; this is prevalent in grains such as corn, wheat, and rice. The source of nutrients is important because the seedling often begins its development underground and cannot perform photosynthesis right away.

triploid ($3n$) cell A cell containing three sets of an organism's chromosomes.

endosperm [Gk. *endo*: within + *sperma*: seed] A specialized triploid seed tissue found only in angiosperms; contains stored nutrients for the developing embryo.

The remaining cells of the male and female gametophytes—the antipodal cells, the remaining synergid, and the pollen tube nucleus—degenerate as the embryo begins to develop.

Double fertilization, a hallmark of angiosperms, is so named because it involves two cell fusion events:

double fertilization In angiosperms, a process in which the nuclei of two sperm fertilize one egg. One sperm's nucleus combines with the egg nucleus to produce a zygote, while the other combines with the same egg's two polar nuclei to produce the first cell of the triploid endosperm (the tissue that will nourish the growing plant embryo).

One sperm cell fuses with the egg cell.

The other sperm cell fuses with the central cell.

The fusion of a sperm cell with the central cell to form the trip-loid endosperm nucleus is one of the defining characteristics of angiosperms.

Embryos develop within seeds contained in fruits

Fertilization initiates the highly coordinated growth and development of the embryo, endosperm, integuments, and carpel. The integuments—protective tissue layers surrounding the ovule—develop into the seed coat, and the ovary wall becomes the outer layers of the fruit that encloses the seed (see [Figure 37.6A](#)).

In [Chapter 36](#) you learned about the events in plant embryonic development and its hormonal control. As seeds develop, they prepare for dispersal and dormancy by losing up to 95 percent of their water content. You can see this desiccation by comparing corn grains (e.g., popcorn) with ripe corn from the cob. A dry seed is still alive; it has protective proteins that keep its cells in a living state.

In angiosperms, the ovary—together with the seeds it contains— develops into a fruit after fertilization has occurred. Fruits have two main functions:

- . They aid in seed dispersal.
- . They protect the seed from damage by animals and infection by microbial pathogens.

A **fruit** may consist of only the mature ovary and seeds, or it may include other parts of the flower. Some species produce fleshy, edible fruits, such as peaches and tomatoes, whereas the fruits of other species are dry ([Figure 37.6](#)).

fruit In angiosperms, a ripened and mature ovary (or group of ovaries) containing the seeds. Sometimes applied to reproductive structures of other groups of plants.

(A) Seed and fruit

(B) Garden pea

(C) Tomato

(D) Corn

Figure 37.6 Angiosperm Fruits There are a variety of fruits, but all have a seed containing the embryo, surrounded by a fruit that comes from the wall of the ovary.

The diverse forms of fruits reflect the varied strategies plants use to disperse their progeny. Because plants cannot move, their progeny need some mechanism for separating themselves from their parents. Wide dispersal of progeny may not always be advantageous, however. If a plant has successfully grown and reproduced, its location is likely to be favorable for the next generation too. Some offspring do indeed stay near their parents. This is the case in many tree species, whose seeds simply fall to the ground. However, this strategy has several potential disadvantages. If the species is a perennial, the offspring that germinate near their parents will be competing with their parents for resources, which may be too limited to support a dense population. Furthermore, even though local conditions were good enough for the parent to produce at least some seeds, there is no guarantee that conditions will still be good the next year, or that they won't be better elsewhere. Thus in many cases seed dispersal is vital to a species' survival.

Many fruits help disperse seeds over substantial distances, increasing the probability that at least a few of the seeds will find suitable conditions for germination and growth to sexual maturity. Some wind-dispersed seeds have fruits with "wings," like those of the familiar maple. In other cases, the fruits and seeds are tiny, and they include feathery structures, such as in this thistle:

Other fruits, such as these burs, attach themselves to animals (or to your clothes and shoes):

Water disperses some fruits; coconuts have been known to float thousands of miles between islands. Seeds swallowed whole by an animal along with fruits such as berries travel through the animal's digestive tract and are deposited some distance from the parent plant.

Biologists are beginning to understand the relationships between seed development (from ovules) and fruit development (from carpels). Some seedless fruits, such as varieties of watermelons and grapes, develop when fertilization occurs, but the embryo then aborts. In other cases, such as bananas, the fruit develops without fertilization. In most cases, however, fruit development does not occur in the absence of fertilization. Several years ago a farmer in Spain who grows sugar apples (*Annona squamosa*) noticed a seedless fruit and brought it to the attention of scientists. A single gene was subsequently identified whose mutated form results in this seedless phenotype. The wild-type version of this gene encodes a transcription factor important to the development of the outer tissues of the ovule. The gene is present in the genomes of all angiosperms examined. In the future, therefore, it may be possible to produce other seedless fruits by engineering mutations in this gene.

Seed development is under hormonal control

[Chapter 36](#) described the role of the gibberellin hormones in the mobilization of stored macromolecules in the seed endosperm during germination. The development of seeds is under the control of a different hormone, **abscisic acid (ABA)**. (Unfortunately, its name is misleading, because it does not directly control leaf abscission.) Most plant tissues make ABA, and like other plant hormones, it has multiple effects (see [Table 36.2](#)). During early seed development the ABA level is usually low, and it rises as the seed matures. This increase stimulates the endosperm to synthesize seed storage proteins. It also stimulates the synthesis of proteins that prevent cell death as the seeds dry.

abscisic acid (ABA) (ab sighs' ik) A plant growth substance with growth-inhibiting action. Causes stomata to close; involved in a plant's response to salt and drought stress.

ABA also keeps the developing seed from germinating on the plant before it dries. Premature germination, termed **vivipary**, is undesirable in seed crops (such as wheat) because the grain is damaged if it starts to sprout. Viviparous seedlings are also unlikely to survive if they remain

attached to the parent plant and are unable to establish themselves in the soil. Mutant strains of corn that are insensitive to ABA have viviparous seeds, indicating the importance of ABA in preventing precocious germination.

vivipary Premature germination in plants.

The general effect of ABA in preventing germination extends to seed dormancy. Seeds tend to stay dormant if their ABA levels are high and germinate when the levels go down. This usually occurs as dormancy is broken.

37.1 recap

Flowers contain the organs for sexual reproduction in angiosperms. Plants that use pollen for reproduction have several selective advantages. After fertilization, the flower develops into seed(s) and fruit. The selective advantages of seeds and fruits include long-term viability and multiple modes of dispersal.

learning outcomes

You should be able to:

- Compare the processes of male and female gamete formation.
- Describe the mechanisms that guide the growth of a pollen tube.
- Describe and compare two methods for preventing self-fertilization in angiosperms.
- Analyze the relationship between the diversity of fruits and their ability to disperse seeds.
- Relate fruit development to seed development.

1. How would plant reproduction be affected if the pollen tube failed to grow and develop properly?
2. How do the final products of meiosis in megagameto-phytes and microgametophytes differ, and how are these differences important to sexual reproduction?
3. Thompson Seedless grapes are produced from triploid plants. Explain why these grapes are seedless. Describe the role played by the flower in fruit formation when no seeds are being formed.
4. What is the selective advantage for the development of many diverse types of fruits?

We have now traced the sexual life cycle of angiosperms from the flower to the gametophytes, pollination, fertilization, and the dispersal of seeds. We discussed seed germination and seedling development in [Chapter 36](#), and vegetative plant growth in [Chapter 33](#). Next we look at the rest of the angiosperm life cycle—the transition from the vegetative to the flowering state—and how this transition is regulated.

*** connect the concepts** Flower structure evolved over time. Natural selection has favored floral features that have increased the likelihood of successful pollination. [Key Concepts 28.3](#) and [56.4](#) describe how angiosperms coevolved with animal pollinators and how ecological communities are formed through interactions among plant and animal species.

*** connect the concepts** As described in [Key Concept 28.3](#), flowers known as perfect flowers have functioning megasporangia and microsporangia. Perfect flowers are thus capable of self-pollination, which is usually disadvantageous. Various mechanisms have evolved in perfect flowers to prevent "selfing"; one is described in [Figure 28.13](#).

37.2 Hormones and Signaling Determine the Transition from the Vegetative to the Reproductive State

Flowering is one of the major events in a plant's life. Flowering requires a reallocation of energy and materials away from making more non-reproductive plant parts (vegetative growth) to making flowers and gametes (reproductive growth). Once a plant is old enough, it can respond to internal or external signals to initiate reproduction. Flowering can happen right at maturity as part of a predetermined developmental program or in response to environmental cues such as light or temperature.

focus your learning

Although in terms of flowering, many plants are classified as either short-day plants (SDPs) or long-day plants (LDPs), night length is actually the cue that controls flowering.

Receptors for the photoperiodic signal for flowering are located in the leaf, and a signal travels to the apical meristem.

The protein florigen converts a vegetative meristem into a reproductive meristem. Several genes are involved in the regulation and transport of florigen.

Temperature or gibberellin can induce flowering in some plants.

Flowering occurs at specific places and specific times

Plants fall into three categories depending on when they mature and initiate flowering, and what happens after they flower:

- **Annuals** complete their lives in one year. This class includes many crops important to the human diet, such as corn, wheat, rice, and soybean. When the environment is suitable, these plants grow rapidly, with little or no secondary growth. After flowering, they use most of their materials and energy to develop seeds and fruits, and the rest of the plant withers away.

annual A plant whose life cycle is completed in one growing season. (Contrast with biennial, perennial.)

- **Biennials** take 2 years to complete their lives. They are much less common than annuals and include carrots, cabbage, and onions. Typically, biennials produce only vegetative growth during the first year and store carbohydrates in underground roots (carrot) and stems (celery). In the second year they use most of the stored carbohydrates to produce flowers and seeds rather than vegetative growth, and the plant dies after seeds form.

biennial A plant whose life cycle includes vegetative growth in the first year and flowering and senescence in the second year. (Contrast with annual, perennial.)

- **Perennials** live 3 or more—sometimes many more—years. Maple trees can live up to 400

years. Perennials include many trees and shrubs, as well as wildflowers. Typically these plants flower every year but stay alive and keep growing for another season; the reproductive cycle repeats each year. However, some perennials (e.g., century plant) grow vegetatively for many years, flower once, and die.

perennial (per ren' ee al) [L. *per*: throughout + *annus*: year] A plant that survives from year to year. (Contrast with annual, biennial.)

No matter what type of life cycle they have, angiosperms all make the transition to flowering. The first visible sign of a transition to the flowering state may be a change in one or more apical meristems in the shoot system. As you saw in [Chapter 33](#), meristems have a pool of undetermined cells. During vegetative growth, a shoot apical meristem continually produces leaves, axillary buds, and stem tissues ([Figure 37.7A](#)) in a kind of unrestricted growth called indeterminate growth (see [Key Concept 33.3](#)).

Figure 37.7 Flowering and the Apical Meristem A vegetative apical meristem (**A**) grows without producing flowers. Once the transition to the flowering state is made (**B**), inflorescence meristems give rise to bracts and to floral meristems (**C**), which

become the flowers.

Flowers may appear singly or in an orderly cluster that constitutes an [inflorescence](#). If a vegetative apical meristem becomes an [inflorescence meristem](#), it stops making leaves and axillary buds and produces other structures: smaller leafy structures called bracts, as well as new meristems in the angles between the bracts and the stem ([Figure 37.7B](#)). These new meristems may also be inflorescence meristems, or they may be [floral meristems](#), each of which gives rise to a flower.

inflorescence A structure composed of several to many flowers.

inflorescence meristem A meristem that produces floral meristems as well as other small leafy structures (bracts).

floral meristem In angiosperms, a meristem that forms the floral organs (sepals, petals, stamens, and carpels).

Each floral meristem typically produces four consecutive whorls or spirals of organs—the sepals, petals, stamens, and carpels discussed earlier in the chapter—separated by very short internodes, keeping the flower compact ([Figure 37.7C](#)). In contrast to vegetative apical meristems and some inflorescence meristems, floral meristems are responsible for determinate growth—growth of limited duration.

A cascade of gene expression leads to flowering

The genes that determine the transition from shoot apical meristems to inflorescence meristems and from inflorescence meristems to floral meristems have been studied in model organisms such as *Arabidopsis*.

MERISTEM IDENTITY GENES

Expression of two [meristem identity genes](#) initiates a cascade of further gene expression that leads to flower formation. These genes encode the transcription factors LEAFY and APETALA1, which together are necessary and sufficient for determining the transition to flowering. Evidence for the roles of these factors comes from both genetic and plant transformation experiments. For example, a mutant allele of the *APETALA1* gene leads to continued vegetative growth, even if conditions are suitable for flowering. However, if the wild-type *APETALA1* gene is coupled with a constitutive (always on) promoter and used to transform *Arabidopsis* plants, the plants will flower prematurely, regardless of environmental conditions. This is powerful evidence that APETALA1 plays a role in switching meristem cells from a vegetative to a reproductive fate (see [Figure 37.7B](#)).

meristem identity genes In angiosperms, a group of genes whose expression initiates flower formation, probably by switching meristem cells from a vegetative to a reproductive fate.

FLORAL ORGAN IDENTITY GENES

The products of the meristem identity genes trigger the expression of [floral organ identity genes](#). They encode transcription factors that determine whether cells in the floral meristem will be sepals, petals, stamens, or carpels.

floral organ identity genes In angiosperms, genes that determine the fates of floral

meristem cells; their expression is triggered by the products of meristem identity genes.

For example, *AGAMOUS* is a ***class C gene** that causes cells determined to be part of the flower to form stamens and carpels. Floral organ identity genes often become activated in response to external cues (day length, temperature) or internal cues (hormones). We begin with day length, or photoperiod.

Photoperiodic cues can initiate flowering

The study of how light affects the transition to flowering began with two observations in the early twentieth century:

Normally, tobacco grows to about 1.5 meters tall before flowering in the summer, but a variety called Maryland Mam-moth grows to an amazing 5 meters. Farmers in Virginia were frustrated because they could not easily get seeds from this luxuriant plant for successive crops. Instead of flowering, it continued to grow until the late fall frost killed it.

Because of improvements in agricultural techniques, soybean yields became so great that it was hard for farmers to harvest all the plants at once. Hoping to stagger the harvests, farmers tried planting the seeds in groups several weeks apart, but all resulting plants nevertheless formed flowers and seeds at the same time.

The explanation for both of these observations was the same: the signal that set the plant's shoot apical meri-stems on the path to flowering was the length of daylight, or **photoperiod**. When soybeans experience days of a certain length, they flower, regardless of how "old" they are. Maryland Mammoth tobacco *can* flower, but it doesn't do so in Virginia because it dies when the weather there gets cold. Maryland Mammoth is now grown commercially in Florida. You saw another example of the role of photoperiod in the opening investigation of this chapter, dealing with poinsettias.

Scientists used greenhouse experiments to measure the day length required for different plant species to flower. Maryland Mammoth tobacco did not flower if exposed to more than 14 hours of light per day; flowering was only initiated once day length became shorter than 14 hours, as it does in December. Other plants (such as soybean and henbane) flowered only when the days were long (**Figure 37.8**). Control of an organism's responses by the length of day or night is called **photoperiodism**.

Figure 37.8 Day Length and Flowering Flowering of Maryland Mammoth tobacco is initiated when the days become shorter than a critical length. Maryland Mammoth tobacco is thus called a short-day plant. Henbane, a long-day plant, shows an inverse pattern of flowering.

photoperiodism Control of an organism's physiological or behavioral responses by the length of the day or night (the photoperiod).

Plants vary in their responses to photoperiodic cues

Plants that flower in response to photoperiodic stimuli fall into two main classes:

- **Short-day plants (SDPs)** flower only when the day is shorter than a critical maximum. They include coffee, morning glory, Maryland Mammoth tobacco, poinsettias, and chrysanthemums. Thus, for example, you see chrysanthemums in nurseries in the fall and poinsettias in winter.

short-day plant (SDP) A plant that flowers when nights are longer than a critical length specific for that plant's species. (Compare to long-day plant.)

- **Long-day plants (LDPs)** flower only when the day is longer than a critical minimum. Spinach, lettuce, and clover are examples of LDPs. For example, spinach tends to flower in the summer, so for harvesting leaves, it is planted in early spring.

long-day plant (LDP) A plant that requires long days (actually, short nights) in order to flower.
(Compare to short-day plant.)

While there are variations on these two patterns, photoperiodic control of flowering serves an important role: it synchronizes the flowering of plants of the same species in a local population, and this promotes cross-pollination and successful reproduction.

Night length is a key photoperiodic cue that determines flowering

The terms "short-day plant" and "long-day plant" imply that *day length* is the environmental cue that triggers flowering. Actually, the important cue is *night length*, as a series of greenhouse experiments confirmed ([Figure 37.9](#)). In a greenhouse, the overall length of a day or night can be varied, irrespective of the 24-hour natural cycle. For example, if cocklebur, an SDP, is exposed to several long periods of light (16 hours each), it will still flower as long as the dark period between them is 9 hours or longer. This 9-hour inductive dark period also induces flowering even if the light period varies from 8 hours to 12 hours.

Figure 37.9 Night Length and Flowering Greenhouse experiments using cocklebur, a short-day plant, showed that night length, not day length, is the environmental cue that initiates flowering.

Biologists noticed that when the inductive dark period was interrupted by a brief period of light, the flowering signal generated by the long night disappeared. It took several days of long nights for the plant to recover and initiate flowering. Interrupting the day with a dark period had no effect on flowering. A clue as to what occurred in the plant when the flash of light was given came when biologists determined the action spectrum for the wavelengths of light that were effective. As with lettuce seed germination (see [Figure 36.12](#)), red light was most effective at breaking the "night" stimulus, and its effect was reversible by far-red light (**Investigating Life:**

The Flowering Signal). Later, the photoreceptor involved was identified as a phytochrome.

As described in [Key Concept 36.4](#), phytochromes and a blue-light receptor function together to “entrain” a circadian rhythm in plants. These photoreceptors cycle through active and inactive phases over repeated 24-hour periods. One gene whose expression follows a circadian rhythm is *CONSTANS* (*CO*), which encodes a transcriptional regulator that controls the expression of flowering genes.

Experiments with *Arabidopsis*, an LDP, have shown that photoperiodic flowering times are determined by interactions between photoreceptors and the *CO* protein. *CO* gene expression goes through regular 24-hour cycles with peak expression late in the day. On long days, this occurs in daylight, late in the afternoon, but on short days the peak expression occurs after dark. On long days, the active forms of phytochrome and a blue-light receptor activate pathways that stabilize the *CO* protein, which promotes flowering. This process does not occur on short days.

 **Animation 37.2 The Effect of Interrupted Days and Nights** www.Life11e.com/a37.2

The flowering stimulus originates in a leaf

Early experiments indicated that reception of the photoperiodic stimulus occurs within the leaf. For example, in the LDP spinach, flowering occurred if the leaves were exposed to long-day periods of light, while the shoot apical meristem was masked to simulate short days. Flowering could *not* occur when the leaves were masked to simulate short days, while the bud was exposed to long-day periods of light.

These “masking” experiments were extended to SDP plants as well ([Figure 37.10](#)). Because the receptor of the stimulus (in the leaf) is physically separated from the tissue on which the stimulus acts (the bud meristem), the inference can be drawn that a systemic signal travels from the leaf through the plant’s tissues to the bud meristem. Other evidence that a diffusible chemical travels from the leaf to the bud meristem signal includes the following:

experiment

Figure 37.10A The Flowering Signal Moves from Leaf to Bud

Original Paper: Hamner, K. C. and J. Bonner, 1938. Photo-periodism in relation to hormones as factors in floral initiation and development. *Botanical Gazette* 100: 388–431.

The receptors for photoperiod are in the leaf, but the transition to flowering occurs in the shoot apical meristem. To investigate whether there is a diffusible substance that travels from leaf to bud, Hamner and Bonner exposed only the leaf to the photoperiodic stimulus.

HYPOTHESIS▶ The leaves measure the photoperiod.

METHOD
Grow cocklebur plants (short-day) under long days and short nights. Mask a leaf on some plants and see if flowering occurs.

RESULTS
If even one leaf is masked for part of the day—thus shifting that leaf to short days and long nights—the plant will flower.

CONCLUSION▶ The leaves measure the photoperiod. Therefore some signal must move from the induced leaf to the flowering parts of the plant.

work with the data

Figure 37.10B The Flowering Signal Moves from Leaf to Bud

Original Paper: Hamner, K. C. and J. Bonner, 1938.

In 1938 Karl Hamner at the University of Chicago was working on the role of plant nutrition in flowering. The plant he studied, cocklebur, is a short-day plant that requires 16 hours of darkness to flower. When the plants were kept in 6 hours darkness (16 hours light) in a greenhouse, they did not flower. One day Hamner came to the lab to find all the plants flowering. It turned out that there had been a power outage, and the plants had received a single inductive short day (long night). Realizing that this provided a simple system to study flowering, Hamner invited a major scientist in the field, James Bonner from Caltech, to join him for the summer. The two biologists carried out a series of experiments using the single inductive period that showed that flowering is induced by night length as opposed to day length (see Figure 37.9) and that the flowering signal is received by the leaf from which it travels to a bud, inducing flowering. A Russian plant physiologist, Mikhail Chailakhyan, named this signal florigen. More recently, the molecular nature of this signal was described.

QUESTIONS▶

1. Intact cocklebur plants (6) or plants with their leaves removed (6) were placed in the inductive (short-day) photoperiod. After 14 days, the researchers obtained the results in [Table A](#). Based on these data, which part of the plant senses the photoperiod?

Table A

Treatment	Number of plants that flowered
No inductive period, intact plant	0
Inductive period, intact plant	6
Inductive period, leaves removed	0

2. Cocklebur plants were treated so that a single leaf was exposed to the inductive (short) photoperiod while the rest of the plant received the long photoperiod. The results obtained after 18 days are shown in [Table B](#). What do these results indicate about the location of the receptor for flowering?

Table B

Treatment	Number of plants	Result
Untreated	6	Vegetative
Treated, one leaf	32	Flower

3. What do the data tell you about the signal generated by the plant in response to photoperiod and that induces flowering in the apical meristem?

A similar **work with the data** exercise may be assigned in **LaunchPad**.

investigatinglife

experiment

Original Paper: Hendricks, S. B. and H. W. Siegelman. 1967. Phytochrome and photoperiodism in plants. *Comparative Biochemistry* 27: 211-235.

Knowing that plants measure night duration, the question became whether the dark hours to which a plant is exposed must be continuous. Using SDPs and LDPs as test subjects, Karl Hamner and James Bonner demonstrated that this was the case by interrupting the night with short bursts of light. Sterling Hendricks and William Siegelman repeated the experiments using light of different wavelengths to gain information about the photoreceptor involved.

work with the data

Original Paper: Borthwick, H. A., S. B. Hendricks and M. W. Parker. 1952. The reaction controlling floral initiation. *Proceedings of the National Academy of Sciences USA* 38: 929–934.

QUESTIONS▶

1. Plants were grown as seedlings in long-night conditions (12 h dark). After exposure to red light in the middle of the night, groups of four plants were exposed to light a second time and then allowed to resume growth in short-night conditions (8 h dark). After 12 days, the possible presence of a floral meristem was examined by dissection. **Table A** shows the results.

Table A

Wavelength (nm)	Number of plants with a floral meristem after exposure to second light			
	16 min	8 min	4 min	2 min
680	0	0	0	0
700	1	3	0	0
720	3	3	3	1

- Why were the plants grown in short-night conditions prior to evaluation of flowering?
- What can you conclude from the data in terms of the receptor and time needed?

2. Groups of four plants were exposed to red, far-red, or no light at the beginning of the dark period. That is, if there were a 7-hour dark period, the plants were exposed to light just after the day period ended (extending the day). The results are shown in **Table B**. Explain the data in terms of the phytochrome system.

Table B

Length of dark period (h)	Number of plants with a floral meristem		
	No light	660 nm	720 nm
7.0	—	—	4
7.5	—	—	4
8.0	0	0	4
8.5	4	0	4
9.0	4	4	—
9.5	4	4	—

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Activity 37.2 Flowering and Day Length Simulation www.Life11e.com/ac37.2

If a photoperiodically induced leaf is immediately removed from a plant after the inductive dark period, the plant does not flower. If, however, the induced leaf remains attached to the plant for several hours, the plant will flower. This result suggests that something is synthesized in the leaf in response to the inductive dark period, and then moves out of the leaf to induce flowering.

If two cocklebur plants are grafted together, and if only one of the plants is exposed to inductive long nights, both plants flower.

In several species, if an induced leaf from one species is grafted onto another, noninduced plant of a different species, the recipient plant flowers.

The transmissible signal was given a name, **florigen** ("flower inducing"), in 1937, but its chemical nature has been described only in the past decade.

florigen A plant hormone involved in the conversion of a vegetative shoot apex to a flower.

Florigen is a small protein

The characterization of florigen was made possible by genetic and molecular studies of the model plant *Arabidopsis*. Three genes are involved in the signaling response for flowering (**Figure 37.11**).

- FT (FLOWERING LOCUS T)** codes for florigen. FT is a small (20 kilodalton [kDa]) protein that can travel through plasmodesmata. FT is synthesized in the phloem companion cells of the leaf and then diffuses into the adjacent sieve elements. It then is carried through the phloem to the apical meristem. If the *FT* gene is coupled to an active promoter and expressed at high levels in the shoot meristem, flowering is induced even in the absence of an appropriate photoperiodic stimulus.
- CO (CONSTANS)** codes for the transcription factor that activates the synthesis of *FT*. As described above, *CO* expression follows a circadian rhythm, and stabilization of the *CO* protein by photoreceptors allows it to function. Like *FT*, *CO* is expressed in leaf companion cells. If *CO* is experimentally over-expressed in the leaf, flowering is induced. However, if *CO* is overexpressed in the apical meristem, flowering is not induced, indicating that *CO* functions in the leaf.

Figure 37.11 Florigen and Its Molecular Biology Florigen is a protein (FT) made in the phloem companion cells. It travels in the sieve elements from the leaf to the bud meristem. There, florigen combines with another protein to stimulate transcription of genes that initiate flower formation.

- FD (FLOWERING LOCUS D)** encodes a protein that binds to *FT* protein when it arrives in the apical meristem. The FD protein is a transcription factor that, when bound to FT, activates promoters for meristem identity genes, such as *APETALA1* (see **Figure 37.11**). The expression of FD primes meristem cells to change from a vegetative fate to a reproductive fate once FT arrives.

FD (FLOWERING LOCUS D) Gene coding for a transcription factor in the shoot apical meristem that binds to florigen; involved in the induction of flowering.

Before FT was isolated, grafting experiments indicated that many different plant species could be induced to flower by the same chemical signal. Results of molecular experiments confirmed that the *FT* gene is involved in photoperiod signaling in many species:

Transgenic plants (e.g., tobacco and tomato) that express the *ArabidopsisFT* gene at high levels flower regardless of day length.

Transgenic *Arabidopsis* plants that express *FT* homologs from other plants (e.g., rice and tomato) flower regardless of day length.

How is this molecular system related to the photoperiodic stimulus? This has been described in the long-day plant *Arabidopsis*. Recall that the stimulus appears to be phytochrome, which exists in two forms, P_r and P_{fr} . At night, the P_{fr} form gradually is converted back to P_r . The P_r stimulates the breakdown of CO protein in proteasomes. So in the morning and during the day, CO protein levels go down. By the end of the day, P_r levels go down, allowing CO to accumulate. So the key to flowering is a high level of the transcription factor CO, and this in turn is related to a low level of P_r . Now, think of a short night (long day): there is not a lot of dark time for all of the P_{fr} to be converted back to P_r , and a long day also causes more conversion of P_r to P_{fr} . The low level of P_r results in less breakdown of CO protein, and the high level of CO results in the transcription of genes for flowering, such as *FT*. To summarize:

Low $P_r \rightarrow$ more CO $\rightarrow$ more transcription of *FT* $\rightarrow$ flowering

We have considered the photoperiodic regulation of flowering, from photoreceptors in the leaf to florigen that travels from the induced leaf to the sites of flower formation. In some plants, however, flowering is induced by other stimuli. These additional stimuli can function with photoperiodism or independently of it.

Flowering can be induced by temperature or gibberellin

Whereas some plants use the environmental cue of day length to induce flowering, other plants use different mechanisms. These include temperature (another environmental cue) and gibberellin (an internal, hormonal cue).

TEMPERATURE

In some plant species, notably certain cereal grains, the environmental signal for flowering is cold temperature, a phenomenon called **vernalization** (Latin *vernus*, "spring"). In both wheat and rye, we distinguish two categories of flowering behavior. Spring wheat, for example, is a typical annual plant: it is sown in the spring and flowers in the same year. Winter wheat is sown in the fall, grows to a seedling, overwinters (often covered by snow), and flowers the following summer. If winter wheat is not exposed to cold in its first year, it will not flower normally the next year.

vernalization [L. *vernalis*: spring] Events occurring during a required chilling period, leading eventually to flowering.

Studies of *Arabidopsis* have shown how vernalization leads to flowering (**Figure 37.12**). In some strains of *Arabidopsis* a gene called *FLC* [*FLOWERING LOCUS C*] encodes a transcription factor that blocks the FT-FD florigen pathway (see **Figure 37.11**) by inhibiting expression of FT and FD. Cold temperature inhibits the synthesis of FLC protein, allowing the

FT and FD proteins to be expressed, and flowering to proceed. Similar proteins control some steps in vernalization in cereals.

Winter-annual *Arabidopsis*
without vernalization

Winter-annual *Arabidopsis*
with vernalization

Figure 37.12 Vernalization A genetic strain of *Arabidopsis* (winter-annual *Arabidopsis*) requires vernalization for flowering. Without it, the plant is large and vegetative (left), but with the cold period it is smaller and flowers (right).

***Epigenetics** plays an important role in the inhibition of *FLC* gene expression by cold temperature. Before vernalization, the chromatin at the promoter of the *FLC* gene is in a relaxed configuration, with histone protein acetylation lowering the ionic attraction of these proteins for DNA, which allows transcription ([Figure 37.13A](#)). During vernalization, a gene is expressed whose protein product is involved in the deacetylation of histones on the *FLC* gene. Deacetylation causes the chromatin to be more compact, which blocks *FLC* gene expression ([Figure 37.13B](#)).

Figure 37.13 Chromatin Remodeling during Vernalization **(A)** In the absence of vernalization, *FLOWERING LOCUS C* (*FLC*) is expressed and flowering is repressed. **(B)** Prolonged cold weather leads to chromatin remodeling that represses expression of *FLC*. The absence of *FLC* protein allows flowering genes to be expressed.

Media Clip 37.2 How Plants Remember www.Life11e.com/mc37.2

GIBBERELLIN

Arabidopsis plants do not flower if they are genetically deficient in the hormone gibberellin, or if they are treated with an inhibitor of gibberellin synthesis. These observations implicate gibberellins in flowering. Direct application of gibberellins to *Arabidopsis* buds results in activation of the meristem identity gene *LEAFY*, which in turn promotes the transition to flowering.

Some plants do not require an environmental cue to flower

Several plant species and strains do not require a photoperiod or vernalization to flower, but instead flower on cue from an "internal clock." For example, flowering in some strains of tobacco

will be initiated in the terminal bud when the stem has grown four phytomers in length (recall that stems are composed of repeating units called phytomers; see [Figure 33.1](#)). If such a bud with a single adjacent phytomer is removed and planted, the cutting will flower because the bud has already received the cue for flowering. But the rest of the shoot below the bud that has been removed will not flower because it is only three phytomers long. After it grows an additional phytomer, it will flower. These results suggest that there is something about the *position* of the bud (atop four phytomers of stem) that determines its transition to flowering.

The bud might "know" its position by the concentration of some substance that forms a positional gradient along the length of the plant. Such a gradient could be formed if the root makes a diffusible inhibitor of flowering whose concentration diminishes with plant height. When the plant reaches a certain height, the concentration of the inhibitor would become sufficiently low at the tip of the shoot to allow flowering. What this inhibitor might be is unclear, but there is evidence that it acts by decreasing the amount of FLC, allowing the FT-FD pathway to proceed (just as cold acts on FLC in vernalization). A positional gradient that acts on FLC would be consistent with other mechanisms affecting flowering, which all converge on *LEAFY* and *APETALA1*:

37.2 recap

Flowering of some angiosperms is controlled by night length, a phenomenon called photoperiodism. Low temperatures can induce flowering in some species (vernalization). Some species flower when their stems have grown by a certain amount, independent of environmental cues. All pathways to flowering converge on the meristem identity genes. The photoperiodic flowering stimulus originates in the leaf, and a signaling pathway ends up in the expression of floral identity genes in the bud.

learning outcomes

You should be able to:

- Give evidence showing that night length, rather than day length, is the cue that triggers flowering.
- Describe evidence that a diffusible chemical travels from the leaf to the bud meristem to initiate flowering.
- Describe the three genes involved in florigen production and action, including where they are active, their functions, and their interactions.
- List factors other than photoperiodism and genetic triggering of florigen that can initiate flowering, and give evidence for each.

1. Describe the proteins and mutations that could be involved in the following observations:

- a. A mutant plant flowers without its normal inductive dark period. When a leaf from the mutant plant is grafted onto an unexposed wild-type plant, the recipient plant flowers.
 - b. A mutant plant does not flower when exposed to the normal inductive dark period. When a leaf from a mutant plant that has been exposed to the inductive dark period is grafted onto an unexposed wild-type plant, the recipient plant flowers.
 - c. A plant flowers only after exposure to cold.
 - d. If a gene is experimentally overexpressed in the leaf, flowering is induced. Overexpression of the gene in the shoot apical meristem, however, does not induce flowering.
2. A horticulturist provides cut flowers for many occasions and often requires large numbers of flowers all blooming at the same time. Many of her flowers are normally summer-blooming, or long-day plants. How might she force these flowers to bloom during the winter?
3. Give at least two pieces of evidence supporting the presence of a transmissible substance that moves from leaves to bud meristems to initiate flowering.

You have seen how environmental factors interact with genes to control flowering in angiosperms. The function of flowers is sexual reproduction, which maintains beneficial genetic variation in a population. Many angiosperms, however, also benefit from being able to reproduce asexually.

***connect the concepts** The roles of floral organ identity genes and their protein products are described in [Key Concept 19.3](#). Class A genes are expressed in whorls 1 and 2 (which form sepals and petals, respectively). Class B genes are expressed in whorls 2 and 3 (which form petals and stamens). Class C genes are expressed in whorls 3 and 4 (which form stamens and carpels). See [Figure 19.11](#).

*** connect the concepts** As described in [Key Concept 16.4](#), epigenetic remodeling of chromatin involves loosening the nucleosome-DNA complex, opening up DNA for gene transcription. See [Figure 16.15](#).

37.3 Angiosperms Can Reproduce Asexually

Although sexual reproduction takes up most of the space in this chapter, asexual reproduction accounts for many of the individual plants present on Earth. This fact suggests that in some circumstances asexual reproduction must be advantageous. In fact, many plants reproduce both asexually and sexually. An example is the iris plant, which has beautiful flowers for sexual reproduction but also a rhizome (an underground stem) from which new plants can arise asexually.

focus your learning

Sexual and asexual reproduction provide separate and distinct advantages to plants.

Asexual, or vegetative, reproduction in plants occurs by changes in vegetative (nonreproductive) organs.

In apomixis, flowers produce clones; the technique has the potential to produce self-reproducing hybrids.

We have noted that genetic recombination is one of the advantages of sexual reproduction. Self-fertilization is a form of sexual reproduction, but offers fewer opportunities for genetic recombination than does cross-fertilization. A diploid, self-fertilizing plant that is heterozygous for a certain locus can produce both kinds of homozygotes for that locus plus the heterozygote among its progeny, but it cannot produce any progeny carrying alleles that it does not itself possess. Nevertheless many self-fertilizing plant species produce viable and vigorous offspring.

Asexual reproduction eliminates genetic recombination altogether. A plant that reproduces asexually produces progeny genetically identical to the parent. What, then, is the advantage of asexual reproduction? If a plant is well adapted to its environment, asexual reproduction allows it to pass on to all its progeny a superior combination of alleles, which might otherwise be separated by sexual recombination.

Plants reproduce asexually by several methods

Stems, leaves, and roots are considered vegetative organs and are distinguished from flowers, the reproductive parts of the plant. Asexual reproduction is often accomplished through the modification of a vegetative organ, which is why the term [vegetative reproduction](#) is

sometimes used to describe asexual reproduction in plants. Often the stem is the organ that is modified for vegetative reproduction. Strawberries, for example, produce horizontal stems, called stolons or runners, which grow along the soil surface, form roots at intervals, and establish potentially independent plants. Asexual reproduction by shoot tips is accomplished when the tips of upright branches sag to the ground and develop roots, as in blackberry and forsythia.

vegetative reproduction Asexual reproduction through the modification of stems, leaves, or roots.

Some plants, such as potatoes, form enlarged fleshy tips of underground stems, called tubers, that can produce new plants (from the “eyes”). Rhizomes are horizontal underground stems that can give rise to new shoots. Bamboo is a striking example of a plant that reproduces vegetatively by means of rhizomes. A single bamboo plant can give rise to a stand—even a forest—of plants constituting a single, physically connected entity ([Figure 37.14A](#)).

(A) Rhizomes

(B) Bulbs

(C) Plantlets

The plantlets forming on the margin of this *Kalanchoe* leaf will fall to the ground and become independent plants.

Figure 37.14 Vegetative Organs Modified for Reproduction(A) The rhizomes of bamboo are underground stems that produce plants at intervals. (B) Bulbs are short stems with large leaves that store nutrients and can give rise to new plants. (C) In *Kalanchoe*, new plantlets can form on leaves.

Whereas stolons and rhizomes are horizontal stems, bulbs and corms are short, vertical, underground stems. Lilies and garlic form bulbs ([Figure 37.14B](#)), short stems with many fleshy, highly modified leaves that store nutrients. These storage leaves make up most of the bulb. They can give rise to new plants by dividing or by producing new bulbs from axillary buds. Crocuses, gladioli, and many other plants produce corms, underground stems that function very much as bulbs do. Corms are disclike and consist primarily of stem tissue; they lack the fleshy

modified leaves that are characteristic of bulbs.

Stems are not the only vegetative organs modified for asexual reproduction. Leaves may also be the source of new plantlets, as in some succulent plants of the genus *Kalanchoe* ([Figure 37.14C](#)). Many kinds of angiosperms, ranging from grasses to trees such as aspens and poplars, form interconnected, genetically homogeneous populations by means of suckers—shoots produced by roots. What appears to be a whole stand of aspen trees, for example, may be a clone derived from a single tree by suckers. This is why the leaves of a whole stand of aspens typically turn yellow at the same time.

Plants that reproduce vegetatively often grow in physically unstable soils such as eroding hillsides. Plants with stolons or rhizomes, such as beach grasses, rushes, and sand verbenas, are common pioneers on coastal sand dunes. Rapid vegetative reproduction enables these plants, once introduced, not only to multiply but also to survive burial by the shifting sand; in addition, the dunes are stabilized by the extensive network of rhizomes or stolons that develops. Vegetative reproduction is also common in some deserts, where the environment is often not suitable for seed germination and the establishment of seedlings.

Vegetative reproduction has a disadvantage

Vegetative reproduction is highly efficient in an environment that is stable over the long term. A change in the environment, however, can leave an asexually reproducing species at a disadvantage. A striking example is provided by the demise of the English elm, *Ulmus procera*, which was apparently introduced into England as a clone by the ancient Romans. This tree reproduces asexually by suckers and is incapable of sexual reproduction. In 1967 Dutch elm disease first struck the English elms. After two millennia of clonal growth, the population lacked genetic diversity, and no individuals carried genes that would protect them against the disease. Today the English elm is all but gone from England.

Vegetative reproduction is important in agriculture

One of the oldest methods of vegetative reproduction used in agriculture consists of simply making cuttings of stems, inserting them in soil, and waiting for them to form roots and become autonomous plants. The cuttings are usually encouraged to root by treatment with auxin, a plant hormone.

Woody plants can be propagated asexually by [grafting](#): attaching a bud or a piece of stem from one plant to a root or root-bearing stem of another plant. The part of the resulting plant that comes from the root-bearing "host" is called the [stock](#); the part grafted on is the [scion](#) ([Figure 37.15](#)). The vascular cambium of the scion associates with that of the stock, forming a continuous cambium that produces xylem and phloem. The cambium allows the transport of water and minerals to the scion and of photosynthate to the stock. Much of the fruit grown for market in the United States is produced on grafted trees, as are wine grapes.

grafting Artificial transplantation of tissue from one organism to another. In horticulture, the transfer of a bud or stem segment from one plant onto the root of another as a form of asexual reproduction.

stock In horticulture, the root or root-bearing stem to which a bud or piece of stem from another plant (the scion) is grafted.

scion In horticulture, the bud or stem from one plant that is grafted to a root or root-bearing stem of another plant (the stock).

Figure 37.15 Grafting Grafting—attaching a piece of a plant to the root or root-bearing stem of another plant—is a common horticultural technique. The “host” root or stem is the stock; the upper grafted piece is the scion. In the photo, a scion of one apple variety is being grafted onto a stock of another variety.

Another method widely used for asexual plant propagation is [meristem culture](#), in which pieces of shoot apical meristem are cultured on growth media to generate plantlets, which can then be planted in the field. This strategy is vital when uniformity is desired, as in forestry, or when virus-free plants are the goal, as with strawberries and potatoes.

meristem culture A method for the asexual propagation of plants, in which pieces of shoot apical meristem are cultured to produce plantlets.

In apomixis, flowers are used in asexual reproduction

Some plants produce flowers but use them to reproduce asexually rather than sexually. Dandelions, blackberries, some citrus trees, and some other plants reproduce by the asexual production of seeds, which is called [apomixis](#). In sexual reproduction, seeds form from the union of haploid gametes in the embryo sac. But in apomixis, one of two other things happens:

apomixis (ap oh mix' is) [Gk. *apo*: away from + *mixis*: sexual intercourse] The asexual production of seeds.

- The megasporocyte in the ovule that is supposed to undergo meiosis fails to do so, resulting in a diploid egg cell, which then goes on to form an embryo and seed.
- Diploid cells from the integument surrounding the embryo sac form a diploid embryo sac, and the sac goes on to form an embryo and seed.

In both cases, seed and fruit development proceed normally. But the genetic consequences are profound: *apomixis produces clones*.

Some agriculturally important plants are hybrids that are de-rived by crossing two genetically different varieties. Because these hybrids have two sets of chromosomes that are not homologous to one another, they cannot undergo meiosis and are sterile. This means they cannot form the seeds and fruits that are desired by people. In citrus, apomixis occurs naturally, which gets around this problem. Kentucky bluegrass, a mainstay of lawns, reproduces in this manner as well.

Many important crops, such as corn, are grown as hybrids because the progeny of a cross between two inbred, homozygous genetic strains are often superior to either of their parents, a phenomenon called hybrid vigor (see [Key Concept 12.2](#)). Unfortunately, once farmers have obtained a hybrid with desirable characteristics, they cannot use those plants for further crosses with themselves (selfing) to get more seeds for the next generation. You can imagine the genetic chaos when a hybrid, which is heterozygous at many of its loci (e.g., *AaBbCcDdEe*, etc.), is crossed with itself: there will be many new combinations of alleles (e.g., *AabbCCDdee*, etc.), resulting in highly variable progeny. The only way to reliably reproduce the hybrid is to maintain populations of the original parents to cross again each year. That is exactly what seed companies do. For farmers, it means buying new seeds every year—an expensive proposition.

If a hybrid carried a gene for apomixis, however, it could reproduce asexually, and its offspring would be genetically identical to itself. New hybrids could be developed that would be adapted to specific environments and could be propagated by the farmers on the spot. So an intensive search is on for genes for apomixis that could be introduced into desirable crops and allow them to be propagated indefinitely. Such a gene has been identified in corn, but the yield of the variety that contains it is low.

37.3 recap

Angiosperms may reproduce asexually by means of modified stems, roots, or leaves. Asexual reproduction is advantageous when a plant has a superior genotype well adapted to its environment, but it can decrease the genetic diversity of plant populations. Seeds and fruits, normally the result of sexual reproduction, can form asexually through apomixes.

learning outcomes

You should be able to:

- Compare and contrast sexual and asexual reproduction in plants, including both the end result and the advantages or disadvantages.
- List types of locations where vegetatively reproducing plants might occur, and give reasons for their occurrence in these locations.
- Describe how apomixis occurs and how this might be useful in agriculture.

1. What are the advantages and disadvantages of asexual reproduction in plants? What are the advantages and disadvantages of sexual reproduction?
2. In what types of situations might asexual reproduction in plants be adaptive?
3. The isolation of a mutation in the *Arabidopsis SWI* gene that results in abnormal meiosis has offered insights into apomixis. How would you try to identify other genes or mutations that function along with the gene product of *SWI*, with the goal of producing fully fertile apomictic plants?

You have seen how angiosperms reproduce sexually and asexually. A disadvantage of asexual reproduction is that its genetic inflexibility may leave a population unable to cope with new challenges. In the next chapter we will focus on the mechanisms that have evolved in plants to cope with biological and physical challenges in their environment.

QA How did an understanding of angiosperm reproduction allow floriculturists to develop a commercially successful poinsettia?

Poinsettias are short-day plants, using the long nights of winter as a signal for flowering. In fact, the poinsettia's inductive dark period of 14 hours was among the first described in a flowering plant. To control photoperiod, the plants are grown in greenhouses, where the photoperiod is carefully regulated.

A second important factor in the poinsettia's commercial success was the plant's growth habit. In Mexico, the wild relatives of cultivated varieties grow up to 3 meters tall, with few branches (compare these plants with the 0.5-meter-tall plants in the photo-graph at the opening of this chapter). Paul Ecke found a variety that was much shorter and formed an attractive branching plant with axillary shoots. These compact poinsettias were initially propagated asexually by grafting to native plants.

Many new varieties of poinsettias have been generated by conventional sexual reproduction. You can look for the phenotypes of these varieties next holiday season. They include stiff stems, new colors (such as white), and longer lifetimes for the colorful bracts. How do you think these characteristics have been introduced into the cultivated varieties?

Future directions

Sequencing of the genomes of agriculturally important plants and genetic screening of mutant strains have led to an accumulation of knowledge of genes controlling the transition to flowering. Efforts are under way to use this understanding to breed crops that produce more seeds more often, by conventional means or biotechnology. This has enormous potential for human welfare. Consider legumes, which are in two general clades, most represented by peas and soybeans. The former is a long-day plant that responds to cold (vernalization), while the latter is more acclimated to warm climes and responds to short days to flower. Genes for the photoperiodic response and signal transduction for flowering have been identified for both species. For example, genetic changes in signaling could allow the plants to have more vegetative growth prior to flowering, which might lead to more floral meristems, more flowers, and more seeds.

► 37.1 Most Angiosperms Reproduce Sexually

- Sexual reproduction promotes genetic diversity in a population. The flower is an angiosperm's structure for sexual reproduction.
- Flowering plants have microscopic gametophytes. The megagametophyte is the **embryo sac**, which typically contains eight nuclei in a total of seven cells. The microgametophyte is the **pollen grain**, which usually contains two cells. **Review Figure 37.2, Activity 37.1**

embryo sac In angiosperms, the female gametophyte. Found within the ovule, it consists of eight or fewer cells, membrane bounded, but without cellulose walls between them.

pollen grain [L. *pollin*: fine flour] In seed plants, microscopic grains that contain the male gametophyte (microgametophyte) and gamete (microspore).

- Following **pollination**, the pollen grain delivers **sperm cells** to the embryo sac by means of a **pollen tube**.

pollination The process of transferring pollen from an anther to the stigma of a pistil in an angiosperm or from a strobilus to an ovule in a gymnosperm.

sperm cells See sperm.

pollen tube A structure that develops from a pollen grain through which sperm are released into the megagametophyte.

- Plants have both physical and genetic methods of preventing inbreeding. Physical separation of the gametophytes and genetic **self-incompatibility** prevent self-pollination. **Review Figure 37.4**
- Most angiosperms exhibit **double fertilization**: one sperm cell fertilizes the egg cell, forming a zygote, and the other sperm cell fertilizes the central cell, where its nucleus unites with the two **polar nuclei** to form a triploid **endosperm**. **Review Figure 37.5, Animation 37.1**

polar nuclei In angiosperms, the two nuclei in the central cell of the megagametophyte; following fertilization they give rise to the endosperm.

endosperm [Gk. *endo*: within + *sperma*: seed] A specialized triploid seed tissue found only in angiosperms; contains stored nutrients for the developing embryo.

- Ovules develop into seeds, and the ovary wall and the enclosed seeds develop into a **fruit**. **Review Figure 37.6**

fruit In angiosperms, a ripened and mature ovary (or group of ovaries) containing the seeds. Sometimes applied to reproductive structures of other groups of plants.

- The hormone [abscisic acid \(ABA\)](#) promotes seed development and dormancy.

abscisic acid (ABA) (ab sighs' ik) A plant growth substance with growth-inhibiting action. Causes stomata to close; involved in a plant's response to salt and drought stress.

▶ 37.2 Hormones and Signaling Determine the Transition from the Vegetative to the Reproductive State

- In [annuals](#) and [biennials](#), flowering followed by seed formation usually leads to the death of the rest of the plant. [Perennials](#) live a long time and typically reproduce repeatedly.

annual A plant whose life cycle is completed in one growing season. (Contrast with biennial, perennial.)

biennial A plant whose life cycle includes vegetative growth in the first year and flowering and senescence in the second year. (Contrast with annual, perennial.)

perennial (per ren' ee al) [L. *per*: throughout + *annus*: year] A plant that survives from year to year. (Contrast with annual, biennial.)

- For a vegetatively growing plant to flower, an apical meristem in the shoot system must become an [inflorescence meristem](#), which in turn must give rise to one or more [floral meristems](#). These events are under the influence of [meristem identity genes](#) and [floral organ identity genes](#). **Review Figure 37.7**

inflorescence meristem A meristem that produces floral meristems as well as other small leafy structures (bracts).

floral meristem In angiosperms, a meristem that forms the floral organs (sepals, petals, stamens, and carpels).

meristem identity genes In angiosperms, a group of genes whose expression initiates flower formation, probably by switching meristem cells from a vegetative to a reproductive fate.

floral organ identity genes In angiosperms, genes that determine the fates of floral meristem cells; their expression is triggered by the products of meristem identity genes.

- Some plants flower in response to **photoperiod**. **Short-day plants (SDPs)** flower when the nights are longer than a critical night length specific to each species; [long-day plants \(LDPs\)](#) flower when the nights are shorter than a critical night length. **Review Figure 37.9**

long-day plant (LDP) A plant that requires long days (actually, short nights) in order to flower. (Compare to short-day plant.)

- The mechanism of photoperiodic control involves phytochromes and a circadian rhythm. **Review Investigating Life: The Flowering Signal, Animation 37.2, Activity 37.2**
- A flowering signal, called [florigen](#), is formed in a photoperiodically induced leaf and is translocated to the sites where flowers will form. **Review Figures 37.10, 37.11**

florigen A plant hormone involved in the conversion of a vegetative shoot apex to a flower.

- In some angiosperm species, exposure to low temperatures—[vernalization](#)—is required

for flowering; in others, internal signals (one of which is gibberellin in some plants) induce flowering. **Review** [Figures 37.12](#), [37.13](#)

vernalization [L. *vernal*: spring] Events occurring during a required chilling period, leading eventually to flowering.

▶ 37.3 Angiosperms Can Reproduce Asexually

- Asexual reproduction allows rapid multiplication of organisms that are well suited to their environment.
- [Vegetative reproduction](#) involves the modification of a vegetative organ — usually the stem—for reproduction. **Review** [Figure 37.14](#)

vegetative reproduction Asexual reproduction through the modification of stems, leaves, or roots.

- Horticulturists often **graft** different plants together to take advantage of favorable properties of both [stock](#) and [scion](#). **Review** [Figure 37.15](#)

stock In horticulture, the root or root-bearing stem to which a bud or piece of stem from another plant (the scion) is grafted.

scion In horticulture, the bud or stem from one plant that is grafted to a root or root-bearing stem of another plant (the stock).

- Some plant species produce seeds asexually by [apomixis](#).

apomixis (ap oh mix' is) [Gk. *apo*: away from + *mixis*: sexual intercourse] The asexual production of seeds.

Go to **LearningCurve** (in **LaunchPad**) for dynamic quizzing that helps you solidify your understanding of this chapter. **LearningCurve** adapts to your responses, giving you the practice you need to master each key concept.

► Apply What You've Learned

Review

- 7.2** Receptors for the photoperiodic signal for flowering are located in the leaf, and a signal travels to the apical meristem.
- 7.2** Although in terms of flowering, plants are classified as either short-day plants (SDPs) or long-day plants (LDPs), night length is actually the cue that controls flowering.

Original Papers: Beveridge, C. A. and I. C. Murfet. 1996. The *gigas* mutant in pea is deficient in the floral stimulus. *Physiologia Plantarum* 96: 637-645.

Hecht, V. et al. 2011. The pea *GIGAS* gene is a *FLOWERING LOCUS T* homolog necessary for graft-transmissible specification of flowering but not for response to photoperiod. *The Plant Cell* 23: 147-161.

The garden pea (a long-day plant) is easy to graft, making it useful for studying the presence or absence of mobile signals. A mobile signal will diffuse from a wild-type root stock into a mutant graft that lacks the signal, restoring the signal in the graft. A nonmobile signal will not restore the signal. Grafting has been used to study genes involved in flowering in the pea.

The *gigas* (*gi*) allele in peas is a mutant version of an *FT* gene and encodes an FT-like protein. [Table A](#) compares the phenotypes of the wild type (WT) and the *gi* mutant at different long photoperiods. The results are given as the plant height (number of nodes) at first flowering. Presence of more nodes, or greater height, indicates delayed flowering (i.e., more vegetative growth before flowering occurs). "Veg." at 24 hours indicates that all growth was vegetative; flowering did not occur.

Table A

Strain	Photoperiod (hours of light)		
	12	16	24
gi mutant	54	43	Veg.
WT	20	16	15

A grafting study was done to test whether the *gi* mutant was deficient in the ability to produce the floral stimulus molecule. Stems from 6-day-old plants were grafted, and plants were kept at a 24-hour pho-to-period for 2-3 months. Grafts were either self (WT to WT, or *gi* to *gi*) or reciprocal (WT to *gi*, or *gi* to WT). Results are shown in [Table B](#).

Table B

Graft partners(root/stem)	Node at first flowering
WT/WT	15
<i>gi</i> / <i>gi</i>	Veg.
<i>gi</i> /WT	17
WT/ <i>gi</i>	16

The graphs (at right) show the transcript levels (mRNA expression) of the WT allele (red circles) and the *gigas* allele (blue circles). Values are shown for both an open leaf and for the apex, or site of flowering. The tests were done on long-day plants.

Questions

1. Based on the data in [Table A](#), what is the effect of the *gi* mutant on flowering in the pea plant?
2. Based on the data in [Table B](#), is it likely that the *gi* mutant is deficient in a mobile floral stimulus molecule? Provide evidence for your conclusion.
3. Develop a model describing the pathway of genetic control of flowering in long-day peas. Include the responses of both the normal (WT) *FT* gene and the mutant (*gigas*) *FT* gene.

Can Scientists Breed Disease-Resistant Wheat?

In 1998, William Wagoire, a plant geneticist in Uganda, was astounded to find red blotches (pustules) on the stems of wheat plants he was breeding. Wheat rust (*Puccinia graminis*), the fungus that causes the pustules, had supposedly been rendered almost extinct 25 years previously when a gene from rye plants was crossed into wheat, making it resistant to this fungal disease. This landmark achievement had protected the crop that provides one-third of the human diet from a mold that can devastate it.

Although two generations of farmers worldwide have never seen an epidemic of wheat rust, its history is well known. The ancient Romans invoked a deity, "Robigus," to ward the mold off their crops. Seventeenth-century colonists in Massachusetts almost starved because their wheat got infected with wheat rust. In 1917, an epidemic of wheat rust in the United States reduced the crop by one-third, leading to widespread panic.

Wagoire used DNA markers to identify the strain of wheat rust he had found. Comparing it with known strains stored in a few laboratories, he found that his strain was new and unique. Clearly, Ug99 (for Uganda 1999) had evolved a way to get around the resistance genes in modern wheat.

When wheat stem rust pustules burst, thousands of spores are released, any one of which can be carried by the wind to a susceptible plant. One hectare of an infected wheat field can release more than 10 billion spores. Carried by prevailing winds, the epidemic spread of Ug99 quickly crossed Africa. By 2001 it had infected wheat in Kenya; in 2003 it was in Ethiopia; in 2006 it crossed the Red Sea to Yemen; in 2009 it was in Iran. At the same time, winds carried the spores south to Zimbabwe and South Africa. Biologists fear that Ug99 could reach central Asia and Australia by prevailing winds; spores could reach North America by the "747 route," through international airplane travel. The Borlaug Global Rust Initiative has been set up to try to use knowledge of plant and fungal biology to stop the spread of this disease before it is too late. More than 1,000 scientists from hundreds of institutions are working together to study the pathogen and host, find genes for resistance, and breed wheat strains that have these genes.

QA

How can knowledge of plant and fungal biology be used to prevent the spread of wheat rust?

38.1 Plants Respond to Pathogens with Constitutive and Induced Responses

Thousands of diseases can affect plants. Each is caused by a different strain of pathogen. Plant pathogens—which include bacteria, fungi, protists, nematodes, and viruses—are part of nature, and for that reason alone they merit our study in biology. For example, many diseases affect tomato plants, some of which may be familiar to you from growing tomatoes in your backyard or finding spoiled tomatoes in a neglected area of your kitchen ([Figure 38.1](#)).

Figure 38.1 Diseases of Tomato Plants A wide variety of disease agents cause a variety of symptoms.

Q: As in animals, diseases in plants are caused by a wide variety of organisms. Can you name human diseases caused by the four types of agents described in this figure?

focus your learning

The plant immune system, which is triggered by elicitors, can produce either general or specific

immunity.

Several forms of systemic acquired resistance provide long-term immunity against various pathogens.

Avirulence (*Avr*) gene products in pathogens interact with resistance (*R*) genes in plants to trigger immune responses.

Many plant diseases are named for the symptoms rather than the agent that causes them. For example, the condition called “blight”, characterized by browning and death of plant tissues, can be caused by bacteria, fungi, or oomycetes. Just as medical schools have departments of pathology, many universities in agricultural regions have departments of plant pathology.

Successful infection by a pathogen can have significant effects on a plant, reducing photosynthesis and causing massive cell and tissue death. Like the responses of the human immune system (see [Chapter 41](#)), the responses by which plants fight off disease are varied and fascinating. Plants and pathogens have evolved together in a continuing “arms race”: pathogens have evolved ways to attack plants, and plants have evolved ways to defend themselves against those attacks.

What determines the outcome of a battle between a plant and a pathogen? The key to success for the plant is to respond to information from the pathogen quickly and massively. Plants use both mechanical and chemical defenses in this effort. These defenses can either be:

Constitutive, always present in the plant, or

constitutive Always present; produced continually at a constant rate. (Contrast with inducible.)

Induced, produced in reaction to damage or stress.

induced A process that occurs only under certain conditions or signals.

Physical barriers form constitutive defenses

A plant’s first line of defense is its outer surfaces, which can prevent the entry of pathogens. As [Chapter 33](#) described, the organs of a growing plant that are exposed to the outside environment are largely covered with cutin, suberin, and waxes. These substances not only prevent water loss by evaporation but can also prevent fungal spores and bacteria from entering the underlying tissues. Some fungi get around this defense by secreting enzymes that hydrolyze these substances, breaking them down to gain entry.

Much more important to the plant are the induced resistance mechanisms. Refer to these in **Focus: Key Figure 38.2** as you read the sections that follow.

focus: key figure

Figure 38.2 Signaling between Plants and Pathogens Molecular interactions between plants and pathogens are highly coevolved. The presence of a pathogen stimulates the plant to produce defensive molecules that work in many different ways.

Animation 38.1 **Signaling between Plants and Pathogens** www.Life11e.com/a38.1

Q: Would you expect these defense molecules to be expressed in the cells of roots, leaves, or both?

Plants can seal off infected parts to limit damage

Whereas animals generally repair tissues that have been damaged by pathogens, plants do not. Instead, plants seal off and sacrifice damaged tissues so that the rest of the plant does not become infected. Plants have the option of discarding damaged tissues because most plants, unlike most animals, can replace damaged parts by growing new ones.

Before we look at the details of the defensive process, we consider a key response by plant cells to invasion by pathogens: the rapid deposition of additional polymers on the inside of the cell wall. These macromolecules not only reinforce the mechanical barrier formed by the cell wall, but also block the plasmodesmata, limiting the ability of viral pathogens to move from cell to cell. The polysaccharides also serve as a base on which lignin, a polymer that provides strength and rigidity, may be laid down. Lignin enhances the mechanical barrier, and the toxicity of lignin precursor chemicals makes the cell inhospitable to some pathogens. These lignin building blocks are only one example of the toxic substances that plants use as chemical defenses.

Induced responses to pathogens are controlled by receptors. Plant pathogens cause the host plant to activate various chemical defense responses. A wide range of molecules called **elicitors** have been identified that trigger these defenses. These molecules vary in character, from peptides made by bacteria to cell wall fragments from fungi. Elicitors can also be derived

from fragments of plant cell wall components broken down by pathogens.

elicitors Molecules associated with plant pathogens that attach to specialized receptors in plants to initiate a defensive response.

The responses of plants to elicitors can be described in terms of the “plant immune system.” Two forms of immunity are recognized (see [Figure 38.2](#)):

- *General immunity* is triggered by general elicitors called pathogen associated molecular patterns (PAMPs). PAMPs are usually molecules that are produced by entire classes of pathogens, such as flagellin (found in bacterial flagella) or chitin (found in fungal cell walls). Thus, general immunity is an overall response rather than a response that is triggered by a specific pathogen in a particular plant. PAMPs are recognized by transmembrane receptors called [pattern recognition receptors \(PRRs\)](#), which activate signaling pathways that lead to general immunity.

pattern recognition receptors (PRRs) Proteins expressed by cells of the innate immune system in animals or plants that bind to molecules from pathogens containing pathogen associated molecular patterns (PAMPs).

- *Specific immunity* is triggered by specific elicitors called [effectors](#). Effectors include a wide variety of specific pathogen-produced molecules that enter the plant cell. Once inside the cell, effectors bind to cytoplasmic receptors called R proteins that trigger the specific immunity response.

effector A component of a physiological system that responds to information by *effecting* changes (making change happen) in the internal environment; examples include muscles and the secretory cells of the digestive tract.

Understanding the pathways of pathogen infection is important for agricultural scientists, because pathogens can severely reduce crop production, as you saw in the opening investigation of this chapter. One approach to understanding is to describe the plant genes whose expression is changed after pathogen infection, as mutations in these genes may lead to resistance. Also, comparative genomics can be used: if a gene that confers resistance is found in one species, it may exist in close relatives, and may even be used to create a transgenic crop that is resistant to the pathogen. An example is described in [Investigating Life: A Gene for Resistance to Wheat Rust](#).

General and specific immunity both involve multiple responses

Many of the signaling pathways associated with general and specific immunity are the same, although the latter is specific for particular pathogens in particular plants, and is much stronger than general immunity. Both forms of immunity involve signaling pathways that are triggered by binding between the elicitors (either PAMPs or effectors) and their receptors. These pathways lead to various responses:

Formation of reactive oxygen and NO: Receptor binding triggers the rapid production of nitric oxide (NO) and reactive oxygen species such as superoxide and hydrogen peroxide. These reactive molecules are toxic to some pathogens, and they are components of signal transduction pathways leading to local and systemic (plantwide) defenses.

Callose deposition: The B-1,3-glucan polymer callose is deposited on the inside of the cell wall to strengthen the wall and seal off the cell.

Hormone signaling: Some pathways result in the production of plant hormones, including salicylic acid and jasmonic acid. We will describe the roles of these hormones in immunity later in the chapter.

Changes in gene expression: Signal transduction cascades lead to changes in gene expression. The upregulated genes include pathogenesis-related (PR) genes and genes encoding the production of antimicrobial substances called phytoalexins

A Gene for Resistance to Wheat Rust

experiment

Original Papers: Sambasivam, P. et al. 2013. The gene *Sr33*, an ortholog of barley *Mla* genes, encodes resistance to wheat stem rust race Ug99. *Science* 341: 786–788.

Saintenac, A. et al. 2013. Identification of wheat gene *Sr35* that confers resistance to Ug99 stem rust race group. *Science* 341: 783–786.

Wheat rust, particularly the new strain Ug99 (see the opening investigation of this chapter), is a major pathogen of wheat that can cause significant reduction in grain production. Cultivated wheat is not resistant to this pathogen strain. But *Aegilops tauschii*, a species of goatgrass that grows in the wild and is a genetic relative of cultivated wheat, is resistant. An international research team isolated a gene called *Sr33* that was responsible for this resistance. The gene encodes a cytoplasmic receptor. Meanwhile, Eduard Akhunov at Kansas State University studied another primitive relative of bread wheat called *Triticum monococcum*, which also is resistant to wheat rust. His team isolated another gene for resistance, called *Sr35*.

HYPOTHESIS ▶ A wild relative of wheat carries a gene for resistance to the wheat rust pathogen.

METHOD

- 1 Compare genomes of two barley strains, one susceptible to the mildew fungus and one that is resistant to it.

Susceptible

Resistant

- 2 Isolate barley gene for resistance (*Sr33*) to mildew fungus.

- 3 Using barley gene as a probe, isolate a homologous gene in goatgrass, a wild relative of wheat that is resistant to wheat rust.

- 4 Insert high-expressing resistance gene into bread wheat.

- 5 Test bread wheat for resistance to wheat rust pathogen infection.

RESULTS

Wild-type wheat is infected.

Transgenic wheat is resistant.

CONCLUSION ▶ A gene from a wild relative of wheat can confer resistance to wheat rust in bread wheat.

work with the data

A series of mutations in *Sr33* was generated by mutagenesis and a genetic screen was performed for susceptibility to wheat rust infection (Figure A). The white bars indicate the deleted DNA, and the map location of the *Sr33* gene is noted between the brackets.

Figure A

QUESTIONS

1. The results for the wild-type *Sr33* and mutant E5–E9 *Sr33* are shown in Figure B. What can you conclude about the role of *Sr33* in rust resistance?
2. The bread wheat strain called Felder was made transgenic for a high-expressing *Sr33* gene. It was then exposed to wheat rust. The results are shown in Figure C. What does this transgenic approach indicate about the role of *Sr33* in rust resistance? Compare your conclusion with that of Question 1.
3. *Triticum monococcum* with wild-type *Sr35* (Figure D, left) was compared with two strains of wheat with mutated *Sr35* genes (Figure D, center and right) with regard to infection by wheat rust. What can you conclude about the role of *Sr35* in resistance?
4. Cultivated Felder bread wheat was made transgenic for a high-expressing *Sr35* gene. It was then exposed to the Ug99 strain of wheat rust. The results are shown in Figure E. What does this indicate about the *Sr35* gene?

Figure E

PHYTOALEXINS

Phytoalexins are antibiotics produced by infected plants and are toxic to many fungi and bacteria. Most are small molecules, and each is made by only a few plant species. They are elicited by effectors of pathogenic bacteria and fungi and are made within hours of the onset of infection. Because their antimicrobial activity is nonspecific, phytoalexins can destroy many species of fungi and bacteria in addition to the one that originally triggered their production. Some phytoalexins can also kill the plant cells that produced them, thus sealing off the infection site (the hypersensitive response, discussed below).

phytoalexins Substances toxic to pathogens, produced by plants in response to fungal or bacterial infection.

An example of a phytoalexin is camalexin, made by the model organism *Arabidopsis thaliana*. Its production is induced by a conserved **protein kinase cascade** that is triggered by receptor binding in either general or specific immunity. This protein kinase cascade results in the upregulation of genes encoding enzymes that convert the amino acid tryptophan to camalexin:

Camalexin appears to work by disrupting the cell membranes of invading pathogens.

PATHOGENESIS-RELATED PROTEINS

Plants produce several types of **pathogenesis-related (PR) proteins**. Some are enzymes that break down the cell walls of pathogens. Chitinase, for example, is a PR protein that breaks down chitin, which is found in many fungal cell walls. In some cases the breakdown products of the pathogen cell walls serve as elicitors that trigger further defensive responses.

pathogenesis-related (PR) protein A plant protein involved in systemic acquired resistance whose synthesis is induced in response to an infection by a pathogen such as a fungus.

Another class of PR proteins are the plant defensins, which are similar to defensins produced by animals (see [Key Concept 41.2](#)). These small peptides bind to fungal membranes and are toxic to a wide range of fungal targets, but they are not toxic to plant or animal cells. Other PR proteins may serve as alarm signals to plant cells that have not yet been attacked. In general, PR proteins appear not to be rapid-response weapons; rather, they act more slowly, perhaps after other, faster responses have blunted the pathogen's attack.

Specific immunity is genetically determined

Pathogenic effectors are molecules made inside host plant cells by invaders. Often, these effectors block some aspect of ***plant immunity**. For example, many effectors are proteases that break down specific plant proteins involved in immune responses. So effectors enable pathogens to overcome general immunity and invade the plant, causing disease. The genes that encode effectors have evolved as part of the “arms race” between pathogens and their host plants.

So the plants fight back. They have evolved intracellular receptors that recognize specific effectors. These receptors are called R (for resistance) proteins. When an R protein binds its ligand (a specific effector), it activates the signal transduction pathways of the specific immunity response. As we mentioned above, specific immunity is stronger than general immunity, and it enables the plant to prevent growth of the pathogen and remain healthy.

R proteins are encoded by **resistance (R) genes**. During the middle of the twentieth century, the plant pathologist Harold Henry Flor, at North Dakota State University, realized that there is a special relationship between R genes and certain pathogen genes named **Avirulence (Avr) genes**. Flor studied strains of the rust fungus (*Melampsora lini*) and the flax plant (*Linum usitatissimum*). He found that specific strains of rust fungus (with particular Avr genes) were able to cause disease only in some varieties of flax—those that *didn't* carry specific R genes. If a flax variety carried the right R gene, it was resistant to those strains of rust fungus. Thus, a particular Avr gene rendered the fungus *avirulent* on flax plants with the corresponding R gene. Flor named this the **gene-for-gene concept**. We now know that Avr genes encode effector molecules that bind to receptors encoded by the R genes, resulting in the specific immunity response (**Figure 38.3**). Hundreds of R genes and their corresponding Avr genes have been identified. A major goal of plant breeders for the past 50 years has been to breed new R genes into crops

to make them more resistant to pathogens.

resistance (*R*) genes Plant genes that confer resistance to specific strains of pathogens.

avrulence (*Avr*) genes Genes in a pathogen that may trigger defenses in plants. (See gene-for-gene concept.)

gene-for-gene concept In plants, a mechanism of resistance to pathogens in which resistance is triggered by the specific interaction of the products of a pathogen's *Avr* genes and a plant's *R* genes.

Figure 38.3 Gene-for-Gene Resistance If a gene in a pathogen that codes for an elicitor "matches" a gene in a plant that codes for a receptor, the receptor binds the elicitor, and a defensive response results.

Q: How do the elicitor and receptor recognize one another?

Specific immunity usually leads to the hypersensitive response

Many signaling pathways and plant responses are shared between general and specific immunity, although in the latter these responses are accelerated and amplified. Furthermore, specific immunity usually leads to a form of programmed cell death called the **hypersensitive response**. When this occurs, plant cells at and near the site of pathogen infection die, forming a necrotic lesion. This cell death deprives the pathogen of nutrients and prevents the spread of the infection. The rest of the plant remains pathogen-free.

hypersensitive response A defensive response of plants to microbial infection in which phytoalexins and pathogenesis-related proteins are produced and the infected tissue undergoes apoptosis to isolate the pathogen from the rest of the plant.

Systemic acquired resistance is a form of long-term immunity

Thus far we have described the events that occur in plant cells at or near the site of invasion by a pathogen. In both general and specific immunity, the infected cells also send hormonal signals to the rest of the plant, stimulating a systemic response. **Systemic acquired resistance** is a general increase in the resistance of the entire plant to a wide range of pathogens. It is not limited to the pathogen that originally triggered it, or to the site of the original infection, and its effect may last as long as an entire growing season.

systemic acquired resistance A general resistance to many plant pathogens following infection by a single agent.

This defensive response is initiated by the plant hormone salicylic acid.

Salicylic acid production is triggered by receptor binding in both general and specific immunity; salicylic acid then functions as a signal that mediates various defense responses. For example, salicylic acid triggers the production of reactive oxygen species and the induction of genes that encode PR proteins. There are many classes of PR proteins, which function in various ways to protect plants against insect attack and against invasion by fungi, bacteria, viruses, and nematodes.

These responses occur at the site of infection and, to a lesser extent, throughout the plant. A derivative of salicylic acid can form a gas that can travel through the air, carrying the defense signal not only to other parts of the same plant but to other nearby plants. Plant-to-plant signaling is also done through mycorrhizae associated with roots. These beneficial fungi (see [Key Concept 35.4](#)) form a network that appears to transmit signals from an infected plant to its neighbors.

Another type of systemic acquired resistance is a more specific defense against viruses with RNA genomes. The plant uses its own enzymes to convert some of the single-strand RNA of the invading virus into double-strand RNA (dsRNA) and to chop that dsRNA into small interfering RNAs (siRNAs) (see [Key Concept 16.5](#)). Simultaneously, some of the viral RNA is transcribed, forming mRNAs that advance the infection. However, the siRNAs interact with another cellular component to degrade those mRNAs, blocking viral replication. The siRNAs spread quickly throughout the entire plant through plasmodesmata, providing systemic resistance.

38.1 recap

Plants have both constitutive and induced defense mechanisms to protect themselves against pathogens. General and specific immunity involve several common signaling pathways, but specific immunity is a stronger response that usually leads to hypersensitive cell death. Specific immunity involves reactions between genetically determined molecules of pathogen and host plant. Systemic acquired resistance provides a longer-lasting, more general immunity throughout the plant.

learning outcomes

You should be able to:

- Compare and contrast general immunity and specific immunity.
- Apply the concept of the genetic "arms race" between plants and their pathogens to the evolution of resistance genes and avirulence genes.
- Describe and discuss the influence of salicylic acid in systemic acquired resistance.

1. A tomato plant can be infected with the fungus *Cladosporium*. The host plant and pathogen can have various genes involved in the hypersensitive response. Complete the table below to show the effects of each fungal strain on tomato leaves:

<i>Cladosporium</i> genotype	<i>Tomato genotype</i>		
	<i>R1R2</i>	<i>R3R4</i>	<i>R1R4</i>
<i>Avr1Avr2</i>			
<i>Avr2Avr3</i>			
<i>Avr1Avr4</i>			

2. Describe how a researcher could determine whether an induced response in a plant cell represents general immunity or specific immunity.
3. A researcher makes a small incision in a leaf of a healthy plant and applies salicylic acid to the cut. How might the researcher expect the plant to respond?

***connect the concepts** Protein kinase cascades are common in signal transduction. See [Key Concept 7.3](#).

***connect the concepts** The concepts of the plant immune response are similar to those of the animal immune response. See [Chapter 41](#).

38.2 Plants Have Mechanical and Chemical Defenses against Herbivores

Herbivores—animals that eat plants—depend on plants for energy and nutrients. Their foraging activities cause physical damage to plants, and they often spread disease among plants as well. While the majority of herbivores are insects ([Figure 38.4](#)), every major class of vertebrates includes at least a few herbivores. Plants cannot evade their consumers by running away, but they have many other ways of protecting themselves against herbivory.

(A) *Locusta migratoria*

(B) *Manduca sexta*

Figure 38.4 Insect Herbivores The great majority of herbivores are insects. (A) Some herbivores, such as this locust, are generalists that will attack nearly any plant. (B) Others are specialists, like this tobacco hornworm, which feeds only on tobacco and related plants.

focus your learning

Plants can defend themselves against herbivores by mechanical methods.

Secondary metabolites are plants' constitutive chemical defenses against herbivory.

Herbivory induces plants to activate elicitors, which in turn activate signal transduction pathways.

Signal transduction pathways involve membrane signaling, reactive oxygen species, and hormone signaling.

The hormone jasmonic acid and its derivatives are key to the expression of many defenses against herbivory.

Plants have mechanical defenses against herbivores

Plants have both constitutive and induced mechanical defenses against herbivores. Constitutive anatomical barriers include trichomes (specialized hairs; see [Figure 38.8](#)) and thorns, spines

that are specialized for defense. An example of an induced mechanical defense is the production of latex. Some plants, such as *Euphorbia* species, produce a thick, white aqueous suspension of cellular debris, oils, and resins called latex when they are injured by an ***herbivore**. Insects trapped by this sticky substance starve to death.

Plants produce constitutive chemical defenses against herbivores

Plants attract, resist, and inhibit other organisms with a wide range of chemicals known as **secondary metabolites**. Primary metabolites are substances such as proteins, nucleic acids, carbohydrates, lipids, and their building blocks, which are produced and used by all living organisms, including plants. Primary metabolites are used in basic cellular processes such as photosynthesis, respiration, and nutrient uptake. Secondary metabolites are substances that are not used for basic cellular processes. Each is found in only certain organisms or groups of organisms.

secondary metabolite A compound synthesized by a plant that is not needed for basic cellular metabolism. Typically has an antiherbivore or antiparasite function.

The more than 10,000 known plant secondary metabolites range in molecular mass from about 70 to more than 380,000 daltons, but most have a low molecular mass (**Table 38.1**). The effects of defensive secondary metabolites on animals are diverse. Some act on the nervous systems of herbivorous insects, mollusks, or mammals. Others mimic the natural hormones of insects, causing some larvae to fail to develop into adults. Still others damage the digestive tracts of herbivores. Some secondary metabolites are toxic to fungal pathogens. Many secondary metabolites are not just used for defense; they have other roles in the plant. For instance, the phenolics called anthocyanins are toxic to insects and bacteria. But they also are pigmented and aid in attracting pollinators, accumulate in vacuoles and so contribute to osmotic pressure in cells, and even regulate dormancy in some plants.

table 38.1 Secondary Metabolites Used in Defense			
Class	Type	Role	Example
Nitrogen-containing	Alkaloids	Neurotoxin	Nicotine in tobacco
	Glycosides	Inhibit electron transport	Dhurrin in sorghum
 Ephedrine (an alkaloid)	Nonprotein amino acids	Disrupt protein structure	Canavanine in jack bean
Nitrogen-sulfur-containing	Glucosinolates	Inhibit respiration	Methylglucosinolate in cabbage
 Methylglucosinolate			
Phenolics	Coumarins	Block cell division	Phytoalexins
	Flavonoids	Inhibit enzymes	Umbelliferone in carrots
 Umbelliferone	Tannins		
Terpenes	Monoterpenes	Neurotoxins	Disrupt reproduction
	Diterpenes	and muscle function	Inhibit
	Triterpenes	transport	Block animal hormones
	Sterols	Deter feeding	
			Pyrethrin in chrysanthemums
			Gossypol in cotton
			Digitalis in foxglove
			Latex

Polyterpenes

in *Euphorbia*

Here is an example of how one of these metabolites works on pathogens. Canavanine is a secondary metabolite whose role is defensive and is based on its chemical structure. Canavanine is an amino acid that is not normally found in proteins, but is very similar to the amino acid arginine, which is found in almost all proteins.

When an insect larva consumes canavanine-containing plant tissue, the canavanine is incorporated into the insect's proteins in some of the places where the mRNA codes for arginine, because the enzyme that charges the tRNA specific for arginine fails to discriminate accurately between the two amino acids (see [Key Concept 14.5](#)). The structure of canavanine, however, is different enough from that of arginine that some of the resulting proteins end up with a modified tertiary structure, and hence reduced biological activity. These defects in protein structure and function lead to developmental abnormalities that kill the insect.

Taking cues from nature, we have practical uses for many plant secondary metabolites or molecules made from them in the lab. Throughout human history, these have formed the basis of herbal medicine as plant extracts are used. As knowledge of chemistry accumulated, people purified the active ingredients of these plants. For instance, the foxglove plant gave us the cardiac drug digitalis.

Plants respond to herbivory with induced defenses

In [Key Concept 38.1](#) we described the defenses that are induced in plants in response to pathogen attack. Plants also respond to wounding and herbivory with induced defenses involving signal transduction pathways. Less is known about the elicitors and receptors involved in these responses, but several classes of chemical elicitors have been identified. These elicitors are either derived from the herbivores themselves or are products of the digestion of plant tissues. For example, the enzymes that insects use to digest plant carbohydrates and lipids can elicit defensive responses. Some elicitors are produced when plant material passes through an herbivore's digestive tract; these elicitors are composed of a fatty acid derived from

the plant and an amino acid derived from the insect gut. One such elicitor, produced by insects feeding on corn plants, has been named volicitin for its ability to induce production of volatile signals that can travel to other plant parts—and to neighboring corn plants—and stimulate their defense responses. In addition, many herbivorous insects lay their eggs on plants, and some components of the fluids secreted during egg laying have been identified as elicitors.

The signal transduction pathways that are activated by herbivory or wounding involve several key components, some of which are shared by the pathways that are induced by pathogens:

Membrane signaling: The cell membrane is the part of the plant cell that is in contact with the environment. Within the first minute after an herbivore strikes, changes in the electric potential of the cell membrane occur in the damaged area. As we will describe in our chapter on the animal nervous system (see [Key Concept 44.2](#)), such changes can be rapidly transmitted as a signal along the cell membrane. In the case of plants responding to herbivory, the continuity of the symplast (see [Figure 34.5](#)) ensures that the signal travels over much of the plant within 10 minutes.

Reactive oxygen species: Both wounding and herbivory trigger the production of reactive oxygen species (such as superoxide and hydrogen peroxide), which act as signaling molecules in pathways that lead to changes in gene expression.

Hormone signaling: Herbivory induces the production of several hormones that stimulate various plant responses. The most important of these is [jasmonic acid \(jasmonate\)](#), which triggers systemic defenses against herbivores.

jasmonic acid (jasmonate) A plant hormone involved in triggering responses to pathogen attack as well as other processes.

 Media Clip 38.1 Plants Can Hear Danger www.Life11e.com/mc38.1

Jasmonates trigger a range of responses to wounding and herbivory

When the plant senses an herbivore-produced elicitor, it makes jasmonate (the ionized form of jasmonic acid) and a variety of jas- monate derivatives. These molecules trigger many plant defenses both at the site of herbivore attack and throughout the plant ([Figure 38.5](#)) . These defenses include the production of specific secondary metabolites and defensive proteins. Jasmonates induce changes in gene expression by binding a transcriptional inhibitor called a JAZ protein. After binding by jasmonate, the JAZ protein is targeted for degradation, and the previously inhibited genes can be expressed.

Activity 38.1 Plants Defenses Simulation www.Life11e.com/ac38.1

Figure 38.5 A Signal Transduction Pathway for Induced Defenses The chain of events initiated by herbivory that leads to the production of a defensive chemical can consist of many steps. These steps may include the synthesis of one or two hormones, binding of receptors, gene activation, and finally, synthesis of defensive compounds.

Protease inhibitors are an important group of defensive proteins that are synthesized in response to insect attack. Once inside an insect's gut, these inhibitors interfere with the digestion of proteins and thus stunt the insect's growth. Jasmonates can also "call for help" by triggering the formation of volatile compounds that attract insects that prey on the herbivores attacking the plant.

Why don't the defensive chemicals that are so toxic to herbivores and pathogens kill the plants that produce them? In some cases the defensive chemicals are directed at organs or systems that are not found in plants, such as the nervous, digestive, or endocrine systems of animals. In addition, plants that produce toxic defensive chemicals sequester them in vacuoles or store them as harmless precursors until used. [Key Concept 56.2](#) describes these methods in more detail.

Plants don't always win the arms race

Milkweeds such as *Asclepias syriaca* store their defensive chemicals in latex in specialized tubes called **laticifers**, which run alongside the veins in the leaves. When damaged, a milkweed releases copious amounts of toxic latex from its laticifers. Field studies have shown that most insects that feed on neighboring plants of other species do not attack laticiferous plants, but there are exceptions. One population of beetles that feeds on *A. syriaca* exhibits a remarkable prefeeding behavior: these beetles cut a few veins in the leaves before settling down to dine. Cutting the veins causes massive latex leakage from the adjacent laticifers and interrupts the latex supply to a downstream portion of the leaf. The beetles then move to the relatively latex-free portion and eat their fill (**Figure 38.6A**).

laticifers (luh tiss' uh furs) In some plants, elongated cells containing secondary plant products such as latex.

(A)

(B)

Figure 38.6 Disarming a Plant's Defense and Applying It (A) This beetle is inactivating a milkweed's defense system by cutting its laticifer supply lines. (B) Collecting latex from a rubber tree in the Philippines.

When latex dries, it becomes rubbery. That's a good adjective, because we have exploited the sticky, moldy properties of dry latex from the tree *Hevea brasiliensis* to turn it into rubber for tires, shoes, adhesives, and condoms, to name a few products ([Figure 38.6B](#)). Because Japan occupied the regions of the world where rubber trees grow, during World War II U.S. and British chemists investigated ways to make synthetic rubber. They analyzed latex, determined its composition of hydrocarbons, and then made rubber in the lab. Today, half of the rubber used worldwide is synthetic.

38.2 recap

Many plants use secondary metabolites as constitutive defenses against herbivory. Other defenses are induced by herbivory through signal transduction pathways. The plant hormone jasmonate stimulates local and systemic responses to herbivores.

learning outcomes

You should be able to:

- Describe physical methods plants use to defend themselves against herbivores.
- Discuss the range of effects that secondary metabolites might have on organisms attacking plants.
- Compare constitutive and induced chemical defenses against herbivores.
- Give examples of types of elicitors known to trigger signal transduction pathways.
- Describe the key components of signal transduction pathways that are activated by herbivory or wounding.
- Describe and analyze the process by which jasmonate defends plants against herbivory.

1. Latex is harvested from certain trees to make rubber. After a region of the tree has been drained of latex, slugs are observed consuming the leaves in that region. What does this indicate about the role of latex in the tree?
2. Tobacco plants produce nicotine as a secondary metabolite. The plants also have induced defenses against herbivores. How would these defenses work together to protect the plant from herbivores?
3. Armyworm larvae feed on corn leaves. They deposit their frass, or waste, in crevices where corn leaves meet stalks. The frass releases chemicals that signal the plant that it is being attacked by armyworms, and the corn plant mounts a defense against armyworms.
 - a. Does this represent a constitutive or an induced defense? Explain your answer.
 - b. How would chemicals in armyworm frass affect the corn plant's response?
4. Explain how plants attacked by herbivores can use jasmonate to "call for help."

A plant's survival depends not only on successful defenses against pathogens and herbivores but also on coping with a sometimes hostile physical environment. Next we will consider how plants deal with environmental stresses.

***connect the concepts** In this chapter we discuss herbivory in the context of how a plant's physiology is affected by an herbivore. See also [Key Concept 55.2](#), which discusses herbivory in

the ecological context of species interactions.

38.3 Plants Can Adapt to Environmental Stresses

Plants are threatened by many biologically harmful aspects of the physical environment, such as drought, waterlogged soils, and extreme temperatures ([Table 38.2](#)). Plants cope with environmental stresses through adaptation or acclimation.

table 38.2 Environmental Stresses on Plants

Condition	Effect on plants
Drought	Reduced water potential, dehydration
Flooding	Reduced O ₂ and respiration
High temperature	Changes in membrane fluidity and in proteins
Low temperature	Changes in membrane fluidity, damage by ice crystals
Salinity	Reduced water potential, dehydration
Metal element toxicity	Disruption of metabolism

Adaptation is genetically encoded strategy for maximizing survival and reproduction in a particular environment. A plant may have structures or biochemical properties that aid in its survival in the face of environmental challenges. Adaptations are the result of evolution by natural selection.

Acclimation is increased tolerance for environmental extremes because of prior exposure to them. An individual plant previously exposed to extreme cold, for example, may be more likely to survive the subsequent winter.

focus your learning

Plants living in water-saturated environments show a variety of adaptations for obtaining oxygen.

Most plant responses to drought are constitutive, but under extreme conditions plants rely on inducible responses.

Only certain plants, called halophytes, are adapted to salty soils; they are able to take up and excrete excess salt.

Phytoremediation takes advantage of hyperaccumulators (plants that take up heavy metals) to clean up toxic environments.

 Media Clip 38.2 Leaves for Every Environment www.Life11e.com/mc38.2

Plants can adapt to dry conditions

Many plants, especially those living in deserts, must cope with extremely limited water supplies. A variety of anatomical and life-cycle adaptations allow plants to survive under these conditions. Many of these adaptations are ways to avoid, reduce, or cope with the inevitable water loss through transpiration that occurs during active photosynthesis. Other adaptations help plants

tolerate the excessive light and heat that are often found in deserts.

DROUGHT AVOIDERS

Some desert plants have no special structural adaptations for water conservation. Instead, these desert annuals, called drought avoiders, simply evade periods of drought. Drought avoiders carry out their entire life cycle—from seed to seed — during a brief period in which rainfall has made the surrounding desert soil sufficiently moist for growth and reproduction (**Figure 38.7**). A different drought avoidance strategy is seen in some African and South American deciduous perennial plants, which shed their leaves in response to drought as a way to conserve water. These plants remain dormant until conditions are again favorable for growth, much as deciduous trees in temperate climates shed their leaves in fall and are dormant until the following spring.

Figure 38.7 Desert Annuals Avoid Drought The seeds of many desert annuals lie dormant for long periods, awaiting conditions appropriate for germination. When they do receive enough moisture to germinate, they grow and reproduce rapidly before the short wet season ends. During the long dry spells, only dormant seeds remain alive.

LEAF STRUCTURES

Most desert plants are not drought avoiders, but rather grow in their dry environment year-round. Plants adapted to dry environments are called **xerophytes** (Greek *xeros*, “dry”). Three structural adaptations are found in the leaves of many xerophytes:

xerophyte (zee’ row fyte) [Gk. *xerox*: dry + *phyton*: plant] A plant adapted to an environment with limited water supply.

- . Specialized leaf anatomy that reduces water loss
- . A thick cuticle and a profusion of hairs over the leaf epidermis, which retard water loss
- . Trichomes that diffract and diffuse sunlight, thereby decreasing the intensity of light impinging on the leaves and the risk of damage to the photosynthetic apparatus by excess light

In some xerophytes the stomata are strategically located in sunken cavities below the leaf surface (known as **stomatal crypts**), where they are sheltered from the drying effects of air currents (**Figure 38.8**). Trichomes surrounding the stomata slow air currents further. Cacti and

similar plants have spines rather than typical leaves, and photosynthesis is confined to the fleshy stems. The spines may help the plants cope with desert conditions by reducing leaf surface area and therefore, water loss. The spines may also deter herbivores.

stomatal crypt In plants, a sunken cavity below the leaf surface in which a stoma is sheltered from the drying effects of air currents.

Figure 38.8 Stomatal Crypts Stomata in the leaves of some xerophytes are located in sunken cavities called stomatal crypts. The trichomes (hairs) covering these crypts trap moist air. Note also the thick cuticle that prevents water loss.

WATER-STORING STRUCTURES

Succulence—the possession of fleshy, water-storing leaves or stems—is another adaptation to dry environments (**Figure 38.9**). This adaptation allows plants to take up large amounts of water when it is available (such as after a brief thunderstorm) and then draw on the stored water during subsequent dry periods. Other adaptations of succulents include a reduced number of stomata and a variant form of photosynthesis (the CAM pathway; see [Key Concept 10.4](#)), both of which reduce water loss.

succulence In plants, possession of fleshy, water-storing leaves or stems; an adaptation to dry environments.

Figure 38.9 Succulence The *Aloe* plant stores water in its fleshy leaves.

ROOT SYSTEMS THAT MAXIMIZE WATER UPTAKE

Roots may also be adapted to dry environments. Cacti have shallow but extensive fibrous root systems that effectively intercept water at the soil surface following even light rains. Mesquite (*Prosopis*) ([Figure 38.10](#)) obtains water through taproots that grow to great depths, reaching water supplies far underground, as well as from condensation on its leaves.

Figure 38.10 Mining Water with Deep Taproots In Death Valley, California, the root of this mesquite tree must reach far beneath the dunes for its water supply.

SOLUTE ACCUMULATION

Xerophytes and other plants that must cope with inadequate water supplies may accumulate high concentrations of the amino acid proline or of secondary metabolites in their vacuoles. This solute accumulation lowers the water potential in the plant's cells below that of the soil, which allows the plant to take up water via osmosis. Plants living in saline environments share

this and several other adaptations with xerophytes, as you will see shortly.

Some plants grow in saturated soils

For some plants, the environmental challenge is too much water, the opposite of that faced by xerophytes. Some plants live in environments so wet that the diffusion of oxygen to their roots is severely limited. These plants have shallow root systems that grow slowly; oxygen levels are likely to be highest near the surface of the soil, and slow growth decreases the roots' need for oxygen.

The root systems of some plants adapted to swampy environments, such as cypresses and some plants that grow in coastal mangrove habitats, have **pneumatophores**, which are extensions that grow out of the water and up into the air (**Figure 38.11A**). Pneumatophores contain lenticels (openings; see **Figure 33.18**) that allow oxygen to diffuse through them, aerating the submerged parts of the root system.

pneumatophores Roots that grow upward out of the water or mud to reach the air and obtain oxygen for the root systems of trees that live in swampy or tidal habitats.

(A)

Pneumatophores are root extensions that grow out of the water, under which the rest of the roots are submerged.

Figure 38.11 Coming Up for Air (A) The roots of these mangroves obtain oxygen through pneumatophores. (B) This scanning electron micrograph of a cross section of a petiole of the yellow water lily shows the structure of the air-filled channels that make up aerenchyma tissue.

Many submerged or partly submerged aquatic plants have large air spaces in the leaf and stem parenchyma and in the petioles. Tissue containing such air spaces is called **aerenchyma** (Figure 38.11B). Aerenchyma stores oxygen produced by photosynthesis and permits its ready diffusion to parts of the plant where it is needed for cellular respiration. Aerenchyma also imparts buoyancy. Furthermore, because aerenchyma contains far fewer cells than most other plant tissues, metabolism in aerenchyma proceeds at a lower rate, so the need for oxygen is much reduced.

aerenchyma In plants, parenchymal tissue containing air spaces.

You may be familiar with rice paddies, where rice grows in a flooded environment. The strains of rice that thrive there—and provide food for millions — have hollow stems like straws, so that air can be supplied to submerged parts of the plant. Remarkably, these strains also have genes that respond to flooding due to heavy rains, by stimulating the plant to grow faster and keep the leaves above the water surface. These genes, appropriately called *SNORKEL-1* and *SNORKEL-2*, encode transcription factors that stimulate the expression of genes involved in cell elongation.

Plants can respond to drought stress

The adaptations of xerophytes for coping with dry environments are generally constitutive—they are always present—and under normal conditions they prevent the plants from experiencing drought stress. When conditions become so dry that even xerophytes are stressed, however, the plants turn to inducible responses. The same responses are found in many other plants, including those that are not adapted to grow in dry climates.

When the weather is abnormally dry, the water content of the soil is reduced and less water is available to plants. Water deficits in plant cells have two major biochemical effects:

- . A reduction in membrane integrity as the polar-nonpolar forces that orient the lipid bilayer are reduced
- . Changes in the three-dimensional structures of proteins

Plant growth is reduced when the structure of plant cells is compromised in these ways. Indeed, inadequate water supply is the single most important factor that limits production of our most important food crops.

When plants sense a water deficit in their [*roots](#), a signaling pathway is set in motion that initiates several measures to conserve water and maintain cellular integrity. This pathway begins with the production of the hormone abscisic acid in the roots. This hormone travels from the roots to the shoot, where it results in stomatal closure and initiates gene transcription that leads to other physiological events that conserve water and cellular integrity ([Figure 38.12](#)).

Figure 38.12 A Signaling Pathway in Response to Drought Stress Adaptation drought stress begins in the root with the production of the hormone abscisic acid.

Q: What genes do you think are stimulated by the LEA proteins?

Many plant genes whose expression is altered by drought stress have been identified, largely through research using DNA microarrays, proteomics, and other molecular approaches (see [Chapters 17](#) and [18](#)). One group of proteins whose production is upregulated during drought stress is the late embryogenesis abundant (LEA; pronounced “lee-yuh”) group of proteins. These hydrophobic proteins also accumulate in maturing seeds as they dry out (hence their name). LEA proteins bind to membrane proteins and other cellular proteins to stabilize them, preventing their aggregation during desiccation.

Plants can cope with temperature extremes

Temperatures that are too high or too low can stress plants and even kill them. Plant species differ in their sensitivity to heat and cold, but all plants have their limits. Any temperature extreme can damage cellular membranes.

High temperatures destabilize membranes and denature many proteins, especially some of the enzymes of photosynthesis.

Low temperatures cause membranes to lose their fluidity and alter their permeabilities to solutes.

Freezing temperatures may cause ice crystals to form, damaging membranes.

Plants have both constitutive adaptations and inducible responses for coping with temperature extremes.

ANATOMICAL ADAPTATIONS

Many plants living in hot environments have constitutive adaptations similar to those of xerophytes. These adaptations include hairs and spines that dissipate heat and leaf forms that intercept less direct sunlight.

HEAT SHOCK RESPONSE

The plant inducible response to heat stress is similar to the response to drought stress in that new proteins are made, often under the direction of an abscisic acid-mediated signaling pathway. Within minutes of experimental exposure to raised temperatures (typically a 5 °C-10 °C increase), plants synthesize several kinds of heat shock proteins. Among these proteins are chaperonins, which help other proteins maintain their structures and avoid denaturation. Threshold temperatures for the production of [heat shock proteins](#) vary, but 38 °C is sufficient to induce them in most plants.

heat shock proteins Chaperone proteins expressed in cells exposed to high or low temperatures or other forms of environmental stress.

COLD-HARDENING

Low temperatures above the freezing point can cause chilling injury in many plants, including crops such as rice, corn, and cotton as well as tropical plants such as bananas. Many plant species can acclimate to cooler temperatures through a process called [cold-hardening](#), which requires repeated exposure to cool temperatures over many days. A key change during hardening is an increase in the proportion of unsaturated fatty acids in cell membranes, which allows them to retain their fluidity and function normally at cooler temperatures (see [Figure 3.21](#)). Plants have a greater ability to modify the degree of saturation of their membrane lipids than animals do. In addition, low temperatures induce the formation of proteins similar to heat shock proteins, which protect against chilling injury.

cold-hardening A process by which plants can acclimate to cooler temperatures; requires repeated exposure to cool temperatures over many days.

If ice crystals form within plant cells, they can kill the cells by puncturing organelles and cell membranes. Furthermore, the growth of ice crystals outside the cells can draw water from the cells and dehydrate them. Freeze-tolerant plants have a variety of adaptations to cope with these problems, including the production of antifreeze proteins that slow the growth of ice

crystals.

Plants can adapt to salty soil

A number of toxic solutes are found in soils, but worldwide, no toxic substance restricts angiosperm growth more than ordinary salt (sodium chloride). Saline—salty—habitats support, at best, limited types of vegetation. Saline habitats are found in diverse locales, from hot, dry deserts to moist, cool coastal marshes. Along the seashore, saline environments are created by ocean spray. The ocean itself is a saline environment, as are estuaries, where fresh and salt water meet and mingle. Salinization of agricultural land is an increasing global problem ([Figure 38.13](#)). Even where crops are irrigated with fresh water, sodium ions from the water accumulate in the soil to ever-greater concentrations as the water evaporates.

Figure 38.13 Salty Soil Accumulation of salt from irrigation water with inadequate drainage has caused this soil in central California to become unsuitable for most plant growth.

Saline environments pose an osmotic challenge for plants. Because of its high salt concentration, a saline environment has an unusually negative soil water potential (see [Figure 34.2](#)). To obtain water from such an environment, a plant must have an even more negative soil water potential; otherwise water will diffuse out of its cells, and the plant will wilt and die. Plants in saline environments are also challenged by the potential toxicity of sodium, which inhibits enzymes and protein synthesis.

Halophytes—plants adapted to saline habitats—are found in a wide variety of flowering plant groups. Most halophytes share one adaptation: they take up sodium and, usually, chloride ions and transport those ions to their leaves. The accumulated ions are stored in the central vacuoles of leaf cells, away from more sensitive parts of the cells. Nonhalophytes accumulate relatively little sodium, even when placed in a saline environment; of the sodium that is absorbed by their roots, very little is transported to the shoot. The increased salt concentration in the tissues of halophytes lowers their water potential and allows them to take up water from their saline environment.

halophytes Organisms that can grow in high salinity.

Some halophytes have other adaptations to life in saline environments. Some, for example, have **salt glands** in their leaves. These glands excrete salt, which collects on the leaf surface until it is removed by rain or wind (**Figure 38.14**). This adaptation, which reduces the danger of poisoning by accumulated salt, is found in some desert plants, such as *Frankenia palmeri*, and in some mangroves growing in seawater.

salt glands Glands on the leaves of some halophytic plants that secrete salt, thereby ridding the plants of excess salt.

Figure 38.14 Excreting Salt This saltwater mangrove plant has special salt glands that excrete salt, which appears here as crystals on the leaves.

Salt glands can play multiple roles, as in the desert shrub *Atriplex halimus*. This shrub has glands that secrete salt into small bladders on the leaves. By lowering the water potential of the leaves, this salt not only helps them obtain water from the roots but also reduces their transpirational loss of water to the atmosphere.

The adaptations we have just discussed are specific to halophytes. Several other adaptations are shared by halophytes and xerophytes, including thick cuticles, succulence, and CAM photosynthesis.

Some plants can tolerate heavy metals

Salt is not the only toxic solute found in soils. High concentrations of some heavy metal ions, such as chromium, mercury, lead, and cadmium, are toxic to most plants; many of these ions are more toxic than sodium at equivalent concentrations.

Some places have a lot of heavy metals as a result of normal geological processes. In other places, acid rain leads to the release of toxic aluminum ions in the soil. Human activities, notably the mining of metallic ores, leave localized areas—known as tailings — with high concentrations of heavy metals and low concentrations of nutrients. Such sites are hostile to most plants, and seeds falling on them generally do not produce adult plants.

Some mine tailings are not completely barren. Investigations have shown that certain species of metal-tolerant plants accumulate concentrations of heavy metals that would kill most plants. More than 200 plant species have been identified as **hyperaccumulators** that store large quantities of metals such as arsenic (As), cadmium (Cd), nickel (Ni), aluminum (Al), and zinc

(Zn).

hyperaccumulators Plant species that store large quantities of heavy metals such as arsenic, cadmium, nickel, aluminum, and zinc.

Perhaps the best-studied hyperaccumulator is alpine pennycress (*Thlaspi caerulescens*). Before the advent of chemical analysis, miners would use the presence of this plant as an indicator of mineral-rich deposits. Studies of *Thlaspi* and other hyperaccumulators have revealed several adaptive mechanisms of hyperaccumulators:

Increased ion transport into the roots

Increased rates of translocation of ions to the leaves

Accumulation of ions in vacuoles in the shoot

Resistance to the ions' toxicity

Knowledge of these hyperaccumulation mechanisms and the genes underlying them has led to the emergence of **phytoremediation**, a form of bioremediation (see [Key Concept 18.5](#)) that uses plants to clean up environmental pollution. Some phytoremediation projects use natural hyperaccumulators, whereas others use genes from hyperaccumulators to create transgenic plants that grow more rapidly and are better adapted to a particular polluted environment. In either case, the plants are grown in the contaminated soil, where they act as natural “vacuum cleaners” by taking up the contaminants. The plants are then harvested and disposed of to remove the contaminants. Perhaps the most dramatic use of phytoremediation occurred after an accident at the nuclear power plant at Chernobyl, Ukraine (then part of the Soviet Union), in 1986, when sunflower plants were used to remove uranium from the nearby soil. These plants are now being used in Japan to soak up radioactive substances from the Fukushima Daiichi reactor accident in 2011. Sunflowers are now the international symbol of nuclear disarmament ([Figure 38.15](#))!

phytoremediation A form of bioremediation that uses plants to clean up environmental pollution.

Figure 38.15 Phytoremediation Plants that accumulate heavy metals can be used to clean up contaminated soils. Here, sunflowers are growing near a nuclear power plant in France.

38.3 recap

Plants that live in continually dry or water-saturated environments have structural adaptations to cope with those conditions. Mechanisms that protect plants from drought stress are initiated by a signaling pathway involving abscisic acid. Heat shock proteins help plants acclimate to high and low temperatures. Halophytes have several adaptations to saline habitats, most of which involve mechanisms that lower their water potential. Some plants can tolerate heavy-metal-rich soils that are toxic to most other plants.

learning outcomes

You should be able to:

- Analyze and compare different methods by which plants respond to saturated environments.
- Discuss factors that trigger inducible responses to drought in plants, and describe the possible responses.
- Describe, analyze, and evaluate methods by which plants are able to remove excess salt.
- Relate phytoremediation to hyperaccumulating plants, and explain how phytoremediation is applied to restore contaminated environments.

1. In the coming decades, climate change may have significant effects on the growth and productivity of plants, in particular the crops on which we depend for our food. What are the physiological effects, and possible genetic responses, of the following, in terms of plant breeding?
 - a. In Pakistan, reduced rainfall causes a reduction in wheat yields.

- b. In the Mekong Delta of Vietnam, rising sea level inundates rice fields, causing a drastic reduction in yields.
- 2. Irrigation leads to increasing salinization of soil. An agricultural researcher wants to develop grain crops able to withstand higher salt concentrations. What type or types of genes might she add to the genomes of the crop plants, and how would these genes function to help the plant withstand salt?
- 3. One disadvantage of using hyperaccumulators to clean up toxic waste sites is that some hyperaccumulators grow slowly and produce little biomass.
 - a. Why would this be a disadvantage?
 - b. Suggest ways in which this disadvantage might be overcome.

QA How can knowledge of plant and fungal biology be used to prevent the spread of wheat rust?

Today, *Puccinia graminis* strain Ug99 continues its spread and threatens wheat crops worldwide. In the Green Revolution of the 1960s to 1980s, wheat plants were bred to have the gene complexes *Sr24* and *Sr31*, *R* genes that conferred resistance to existing strains of wheat rust fungus. The first strain of Ug99 found in Uganda had *Avr* genes that form elicitor proteins that do not bind to *Sr31* and therefore overcome part of the plant's resistance. Then, in 2006, a new genetic variant of Ug99 was found in Kenya with additional *Avr* genes that allow the pathogen to overcome the *Sr24* gene resistance as well. Because 90 percent of the wheat grown in the world has no resistance to this new strain of Ug99, an intensive search is under way for additional wheat resistance genes. In the regions where Ug99 infections are now present, occasional wheat plants grow that are resistant. Samples of both wheat plants and fungus are sent to laboratories, where, under high security and sterility, they are tested and examined for *Avr* and *R* genes. In addition, seeds from thousands of varieties of wheat, collected from all over the world, are being grown into seedlings and examined for *R* genes.

Future directions

The roles of the hormones jasmonic acid and salicylic acid in plant immunity are well described. It is now apparent that other hormones are involved as well. This is yet another example of crosstalk between signaling pathways. Auxins affect the architecture of the plant cell wall, leading to wall loosening. But this has a downside, making the plant's mechanical defenses less effective, and pathogens grow more readily in loose walls. Auxins can also interrupt other hormone signaling pathways, leading to reduced immunity. So there is a trade-off between growth and disease susceptibility. Perhaps most dramatically, certain bacteria have a complete biochemical pathway for the synthesis of auxins, so that when they enter a plant, auxins are secreted and overgrowth occurs. We are only beginning to understand the direct and indirect relations between hormones and plant immunity.

► 38.1 Plants Respond to Pathogens with Constitutive and Induced Responses

- Plants and pathogens have evolved together in a continuing “arms race”: pathogens have evolved mechanisms for attacking plants, and plants have evolved mechanisms for defending themselves against those attacks.
- Constitutive** defenses include plants’ ability to strengthen their cell walls and block plasmodesmata when attacked, limiting the ability of viral pathogens to move from cell to cell.

constitutive Always present; produced continually at a constant rate. (Contrast with inducible.)

- Induced** defenses are triggered by a wide range of molecular elicitors and fall into two main categories: general immunity and specific immunity. **Review Focus: Key Figure 38.2, Animation 38.1**

induced A process that occurs only under certain conditions or signals.

- There is an ongoing search for genes involved in plant defense. **Review Investigating Life: A Gene for Resistance to Wheat Rust**
- The **gene-for-gene concept** depends on a match between a plant’s **resistance (R) genes** and a pathogen’s **Avirulence (Avr) genes**. **Review Figure 38.3**
- In the **hypersensitive response** to infection by bacteria or fungi, cells produce two kinds of defensive molecules: **phytoalexins** and **pathogenesis-related (PR) proteins**. Some cells around the infected area die, sealing off the pathogens and the damage they have caused.
- The hypersensitive response is often followed by **systemic acquired resistance**, in which salicylic acid activates further synthesis of defensive compounds.
- Plants use RNA interference to develop specific immunity to invading RNA viruses.

► 38.2 Plants Have Mechanical and Chemical Defenses against Herbivores

- Some plants produce **secondary metabolites** as defenses against herbivores. **Review Table 38.1**
- Hormones, including **jasmonates**, participate in signal transduction pathways leading to the production of defensive compounds. **Review Figure 38.5 Activity 38.1**
- Plants protect themselves against their own toxic defensive chemicals by sequestering them in vacuoles or storing them as harmless precursors until used.

► 38.3 Plants Can Adapt to Environmental Stresses

- Plants cope with environmental stresses by **adaptation** (genetically encoded resistance) or **acclimation** (increased tolerance). **Review Table 38.2**
- Xerophytes** are plants that are adapted to dry environments.

- Some xerophytic adaptations are structural, including thickened cuticles, specialized trichomes, **stomatal crypts**, **succulence**, and long taproots.
- Some plants accumulate solutes, making their water potential lower so they can tolerate drought.
- Adaptations to water-saturated habitats include **pneumatophores**, extensions of roots that allow oxygen uptake from the air, and **aerenchyma**, tissue in which oxygen can be stored and used to supply the rest of the plant.
- A signaling pathway involving abscisic acid initiates a plant's response to drought stress. **Review [Figure 38.12](#)**
- Membranes and proteins can be damaged by extremely high or low temperatures. Plants respond to extreme temperatures by producing **heat shock proteins**.
- Some plants undergo **cold-hardening**, an acclimation process that includes changes in membrane lipids and production of heat shock proteins.
- Some plants resist freezing by producing antifreeze proteins.
- Most **halophytes** accumulate salt. Some have **salt glands** that excrete salt to the leaf surface.
- Some plants living in soils that are rich in heavy metals are **hyperaccumulators** that take up large amounts of those metals into their tissues.
- **Phytoremediation** is the use of hyperaccumulating plants or their genes to clean up environmental pollution.

See [Activity 38.2](#) for a concept review of this chapter.

► Apply What You've Learned

Review

- 8.2 Secondary metabolites are plants' constitutive chemical defenses against herbivory.
- 8.2 Herbivory induces plants to activate elicitors, which in turn activate signal transduction pathways.
- 8.2 The hormone jasmonic acid and its derivatives are key to the expression of many defenses against herbivory.

Original Paper: Halitschke, R., U. Schittko, G. Pohnert, W. Boland, and I. T. Baldwin. 2001. Molecular interactions between the specialist herbivore *Manduca sexta* and its natural host *Nicotiana attenuata*. *Plant Physiology* 125: 711-717.

Herbivores feed on the tobacco plant *Nicotiana attenuata*, which defends itself by producing secondary metabolites, most notably nicotine. Researchers did a series of experiments comparing two different types of responses in *Nicotiana*: response to a wound (mechanical damage), such as that done by animals, and response to herbivory by the caterpillar of the tobacco hornworm, *Manduca sexta*. They questioned whether the plant showed differences in its chemical defenses to these two types of predation.

The researchers exposed leaves on tobacco plants to physical wounds that might occur when a large animal chews the leaves. They also exposed the leaves to wounds along with hornworm secretions called FACs. This simulated the second condition, attack by a hornworm.

In one experiment, researchers measured nicotine production under both conditions and compared the results to those from untreated controls, as shown in [Figure A](#).

Figure A

In a second experiment, the researchers repeated the above two experimental conditions, but after a short period measured the concentration of the signaling molecule jasmonic acid (see [Figure 38.5](#)). The results are shown in [Figure B](#).

Figure B

The hornworm is able to eat tobacco without ill effects. One way it might be able to do this is by suppressing nicotine production in the plants. The hormone ethylene (see [Figure 36.2](#)) suppresses nicotine production. Thus, the researchers measured ethylene in the two conditions of predation, as shown in [Figure C](#).

Figure C

Questions

1. Compare nicotine production in the two types of herbivory. What might account for the difference? Is nicotine production a constitutive or an induced response? Explain your answer.
2. What is the role of jasmonic acid in the plant's response to herbivory? How does it differ from nicotine in its effects?
3. In the graph illustrating jasmonic acid production, compare the plant's response to the wound and to the wound + hornworm FACs. What does the difference in these responses suggest about the importance of the FACs produced by the caterpillar?
4. Compare the production of jasmonic acid and ethylene under the two experimental conditions. What might explain the difference in these two responses?

Heat Limits Physical Performance

The 2008 New York City Marathon took place on a cold, clear, windy day in November. For the third time, the first-place woman in this 41-kilometer race was world record holder Paula Radcliffe. Radcliffe had also been expected to win the women's marathon in the 2004 Olympics. But that race took place on an extremely hot (high of 34°C), humid day in Athens. Overcome by heat stress, Radcliffe collapsed 6 kilometers from the finish line.

Elite runners generally have their best times when temperatures are below 10°C. The 2012 Boston Marathon coincided with an unseasonable April heat wave, with temperatures exceeding 27°C. During the race, 120 runners were rushed to hospitals with severe heat stress.

When a person's internal body temperature rises above 40°C, major organs begin to fail, a condition known as heat stroke. Every year some athletes suffer heat stroke, which leads to death in a high percentage of cases. Soldiers in desert environments are at extreme risk of heat stroke, as are workers in many occupations, including firefighting, agriculture, and construction.

Heat stroke is a particular danger for those who are active in the heat because working muscles generate heat. The blood carries that heat out of the muscles and distributes it throughout the body, raising the temperature of the body's internal tissues. Some of the heated blood flows to the skin, where heat can be lost to the environment, but humans are subject to the problems faced by all mammals in losing excess heat. First, their normal internal temperatures are not far from the environmental temperatures that cause heat stress, so they don't have much of a safety zone. Second, most mammalian skin surfaces are covered with an insulating layer of fur—great for conserving body heat in cold environments, but an impediment to heat loss in warm ones. Even human skin is an insulator.

A major evolutionary adaptation in mammals for heat loss is efficient heat-loss portals of non-furred areas such as the nose, tongue, and footpads. In these areas, specialized blood vessels can open up and act like radiators to disperse heat (conversely, these portals can close down to conserve heat). Humans are not furred, but our evolutionary ancestors were, and we retain these mammalian blood vessel adaptations in our hands, feet, and face (which is why we blush).

QA How can we increase heat loss from the body to protect against heat stress?

39.1 Animals Are Composed of Organs Built from Four Types of Tissues

Animals are amazing in all they do to survive, thrive, and propagate. They live in environments that could not support single cells, they extract energy from the environment, they build complex molecules and structures, they alter their environments, and they reproduce. All of these feats and more depend on complex body components that have evolved since the first appearance of multicellular organisms on this planet. What does it take to be an animal?

focus your learning

Multicellularity enabled the evolution of organisms that are much larger than single-celled organisms can be.

Organs are composed of four tissue types.

How would you build a multicellular animal?

This might seem like a silly question; even bioengineers don't build animals. But as you begin to study animal form and function, or animal physiology, it is instructive to think of all of the problems animals must solve to survive. For example: they must:

extract energy and nutrients from the environment.

build all of the internal structures they need.

eliminate toxins and metabolic waste products.

sense the environment and respond to it in various ways, including movement.

maintain constant conditions in their internal environments.

reproduce.

Single- and multicellular organisms have evolved to conquer these challenges. In fact, single-celled organisms are remarkably abundant and thrive in widely diverse environments.

Multicellular organisms have evolved complex body systems to conquer the same challenges. Given the success of single-celled organisms, why have multicellular animals evolved? How is it advantageous to be multicellular? Multicellularity confers two advantages—large size and the opportunity for cells to specialize.

There are advantages and challenges to getting bigger

Advantages to being bigger include being able to prey on other organisms and also being able to resist or work against forces in the environment, such as wave forces in reefs. There is a problem, however, that limits how big single-celled organisms can get. All exchanges with the environment, such as uptake of nutrients and elimination of wastes, occur across the cell membrane, so the extent of these exchanges is limited by the surface area of the cell membrane. ***Cell surface area** increases with the square of the linear dimension of the cell, but the needs of the cell increase as a function of the volume of the cell, which is a function of the cube of the linear dimension. Thus there is a size limit beyond which single-celled organisms cannot satisfy their needs.

Cell specialization is essential for multicellular animals to grow bigger. If a multicellular animal

consists of only a few layers of cells, those cells can carry out their own exchanges directly with the environment. A good example is a sponge ([Figure 39.1](#)). Bigger organisms have cells that are not in contact with the external environment. The needs of those cells must be supplied by an *internal* environment—extracellular fluid that bathes all the cells of the animal's body. Different cells and groups of cells must be specialized to contribute to the maintenance of that internal environment. Thus each cell contributes to the internal environment, and each cell is supported by that internal environment.

Figure 39.1 No Cell Too Far The sponge *Leucosolenia* is a tube about 2 cm. long with an outer and an inner layer of cells and a jellylike matrix. There are pores between the cells of the tube. The inner cells have flagella that create a current of water in through the pores and out through the opening at the top. The individual cells of this animal can obtain nutrients and oxygen directly from the seawater.

Cell specializations have tremendous adaptive value for even the simplest multicellular animals. Some cells can be specialized for movement, some for intake of food, and some for reproduction. But evolving a specialized function usually comes at the expense of other cellular functions, which may be lost or at least compromised. The specialized cells of an organism thus engage in a kind of collaborative enterprise by providing services for all of the cells of the organism in return for different services provided by other cells. Thus the cells specialized for movement do not have to also capture and process food, and the reproductive cells do not have to move the whole animal to find a mate. For example, male sex cells are motile cells that are good at seeking out nonmotile female sex cells, but the male sex cells have lost the ability to do many other cell functions such as acquire and process food.

There are four tissue types

Specialized cells rarely function alone, but rather as groups of similar cells called [tissues](#). There are many different kinds of cells, but they are all classified as one of four tissue types: epithelial, muscle, connective, and nervous (**Focus: Key Figure 39.2**):

tissue A group of similar cells organized into a functional unit; usually integrated with other tissues to form part of an organ.

Creating Compartments: Epithelial Tissues

Generating Forces: Muscle Tissues

Providing Support: Connective Tissues

Processing Information: Nervous Tissues

Figure 39.2 How to Build an Animal Tissues are the building blocks.

Q: If we consider the functions of skeletal muscle in running, what are roles played by the three other tissue types in this process?

- . **Epithelial tissues** are sheets of cells that create barriers between different compartments and frequently have secretory functions.

epithelial tissue A type of animal tissue made up of sheets of cells that lines or covers organs, makes up tubules, and covers the surface of the body; one of the four major tissue types in multicellular animals.

- . **Muscle tissues** contract to generate forces and movement.

muscle tissue Excitable tissue that can contract through the interactions of actin and myosin; one of the four major tissue types in multicellular animals. There are three types of muscle tissue: skeletal, smooth, and cardiac.

- . **Connective tissues** provide structure and support.

connective tissue A type of tissue that connects or surrounds other tissues; its cells are embedded in a collagen-containing matrix. One of the four major tissue types in multicellular animals, including cartilage, bone, blood, and fat.

- . **Nervous tissues** convey and process information.

nervous tissue Tissue specialized for processing and communicating information; one of the four major tissue types in multicellular animals.

These are very general groupings that reflect developmental origins, but within each group there are various specializations that accommodate different functions. For example, connective tissue includes bones, cartilage, fat, and blood. Epithelial tissue includes the outer layers of skin (epidermis) and many types of secretory cells that produce and release substances internally, such as hormones, and externally, such as sweat and digestive juices. You might think of digestive juices as being secreted internally, but the lumen of the digestive tract is continuous with the external environment. You will learn a lot about the diversity of functions accomplished through specializations of these four tissue types in the chapters that follow.

Organs are built from multiple tissues

Organs are internal structures that carry out specific functions. An organ is composed of an outer covering, or epithelium, and one or more other kinds of tissues. Indeed, most organs include all four tissue types. The gut (digestive tract) is a good example (**Figure 39.3**). Its inner surface is lined with a sheet of columnar epithelial cells. Different types of epithelial cells in this lining secrete hormones or digestive juices or absorb nutrients from the gut. Beneath the epithelial lining is a layer of connective tissue called the mucosa. Within this connective tissue are blood vessels, neurons, and glands (clusters of secretory epithelial cells). Concentric layers of smooth muscle tissue enable the gut to contract to mix food with digestive juices. A network of neurons between the muscle layers controls these movements.

organ [Gk. *organon*: tool] A body part, such as the heart, liver, brain, root, or leaf. Organs are composed of different tissues integrated to perform a distinct function. Organs, in turn, are integrated into organ systems.

Figure 39.3 Tissues Form Organs The organs of the human digestive system, such as the stomach and small intestine, are made up of all four tissue types.

 Activity 39.1 **Tissues and Cell Types** www.Life11e.com/ac39.1

An individual organ is usually part of an organ system, a group of organs that work together to carry out certain functions. The stomach, small intestine, liver, and pancreas, for example, are parts of the digestive system. The structure of an animal involves an organizational hierarchy. Cells form tissues, tissues form organs, organs work together as organ systems, and all work together as a multicellular organism.

39.1 recap

There are limits to how large cells can be because metabolic needs are related to cell volume, and abilities to satisfy those needs are determined by cell surface area. Cell volume grows faster than cell surface area. Multicellularity and cell specialization enabled organisms to grow larger. Groups of similar cells form tissues, and multicellular animals are composed of four tissue types: epithelial, connective, nervous, and muscle. Individual organs include multiple tissue types and are part of organ systems.

learning outcomes

You should be able to:

- Demonstrate an understanding of the factors that limit cell size.

- Describe the advantages of multicellularity.
 - Explain structure-function relationships within an organ.
-

1. What limits the size of single cells?
2. What are the advantages of being a multicellular organism rather than a single-celled organism?
3. Provide an example of how multiple tissue types are involved in the construction of an organ. What does each tissue type contribute to the function of that organ?

Subsequent chapters will describe each of the organ systems in much greater detail. The remainder of this chapter focuses on the mechanisms of control and regulation of the internal environment, using temperature as the example.

***connect the concepts** [Figure 5.2](#) illustrates how cell volume grows faster than cell surface area as cells get bigger.

39.2 Physiological Systems Maintain Homeostasis of the Internal Environment

The evolution of multicellularity made it possible to enclose and therefore create an internal fluid environment that bathed all cells of the organism. Since that internal environment provided for all of the needs of the individual cells, individual cell lines could become specialized as to what they contributed to the internal environment. Just as with people, specialization in one function usually goes hand in hand with losses in other functions. But those functional losses in each cell line were compensated for by the constancy of the internal environment. The evolution of organs composed of multiple tissues and the evolution of informational systems to control organ activities improved the abilities of animals to maintain a constant internal environment. In essence, the evolution of physiological systems to maintain various aspects of the internal environment made it possible for multicellular animals to become larger, and more complex, and allowed them to occupy many different environments.

focus your learning

The needs of cells in the multicellular animal are served through exchanges with the internal environment, which consists of the extracellular fluid.

Homeostasis of the internal environment is maintained through control and regulation of activities of organs and organ systems.

The internal environment is the extracellular fluid that serves all the needs of the cells of the body

Individual cells get their nutrients from the surrounding extracellular fluid (ECF) and dump their waste products into it. A human is about 60 percent water. Two-thirds of that water is intracellular fluid and one-third is the ECF. About 20 percent of the ECF (about 3 liters) is the **blood plasma** that circulates in our blood vessels. The remaining 80 percent (about 11 liters) is the **interstitial fluid** that bathes every cell of the body (**Figure 39.4**). Water and small molecules freely exchange between the interstitial fluid and the blood plasma. Thus nutrients move into the interstitial fluid from the blood plasma, and wastes move into the blood plasma from the interstitial fluid. As long as the composition and physical conditions of the interstitial fluid are held within certain limits, cells are protected from the changes and harsh conditions of the external environment. A stable internal environment makes it possible for an animal to occupy habitats that would kill its cells if they were directly exposed to the external conditions. How is the internal environment kept constant?

blood plasma (plaz' muh) The liquid portion of blood, in which blood cells and other particulates are suspended.

interstitial fluid Extracellular fluid that is not contained in the vessels of a circulatory system.

Figure 39.4 The Internal Environment The extracellular fluid (ECF) is the “internal environment,” and it is about 1.3 of total body water. The ECF is about 20% blood plasma and 80% interstitial fluid. The composition and physiological state of the ECF must remain stable within narrow limits, and maintaining that stability is the job of the body’s organ systems.

The constant composition of the internal environment is always being challenged by the external environment and by the metabolic activities of the cells of the body. Organisms must maintain their internal environment in a state of **homeostasis**—a narrow range of stable and optimal physical and biochemical conditions.

homeostasis (home’ ee o sta’ sis) [Gk. *homos*: same + *stasis*: position] The maintenance of a steady state, such as a constant temperature, by means of physiological or behavioral feedback responses.

If a physiological system fails to function properly, homeostasis is compromised, and cells are damaged and can die. To avoid the loss of homeostasis, organ systems are controlled and regulated in response to changes in both the external and internal environments. The maintenance of homeostasis is a central theme of physiology.

Physiological systems are regulated to maintain homeostasis

The activities of physiological systems are *controlled*—speeded up or slowed down—by actions of the nervous and endocrine systems. But to *regulate* these systems and maintain homeostasis, information is required. As an analogy, think of the thermostat that controls the furnace and air conditioner to regulate the temperature of a house (**Figure 39.5**). The desired temperature is a **set point**, or reference point on the thermostat. The thermostat acts as a **comparator** by sensing the current temperature in the house and comparing that value to the set point. Thus the sensing of the air temperature is **feedback** information. Any difference between the set point and feedback information results in an **error signal**. The error signal is converted into commands to the furnace or air conditioner, turning them on or off.

set point In a regulatory system, the threshold sensitivity to the feedback stimulus.

comparator In a regulatory system, the mechanism for comparing a feedback variable to a set point to generate command signals to effector organs.

feedback In regulatory systems, information about the relationship between the set point of the system and its current state. (Contrast with feedforward information.)

error signal In regulatory systems, any difference between the set point of the system and its current condition.

Figure 39.5 A Thermostat Regulates Temperature A thermostat regulates the temperature of a room by turning the furnace or air conditioner on or off in response to the difference between feedback information (room temperature) and set points that are programmed into the thermostat.

Regulatory systems such as a building thermostat or one of the many physiological regulatory systems described in this book obtain, process, and integrate information. Regulatory systems use that information to issue commands to **effectors** such as muscles or glands that effect changes in the internal environment. Effectors are also called **controlled systems** because their activities are controlled by the neural or hormonal signals from their respective regulatory systems. Important components of any regulatory system are the sensors such as

light-, temperature-, and pressure-sensitive cells that provide feedback information to be compared with internal set points.

regulatory system A system that uses feedback information to maintain a physiological function or parameter at an optimal level. (Contrast with controlled system.)

effector A component of a physiological system that responds to information by *effecting* changes (making change happen) in the internal environment; examples include muscles and the secretory cells of the digestive tract.

controlled system A set of components in a physiological system that is controlled by commands from a regulatory system. (Contrast with regulatory system.)

Negative feedback is information used to counteract the influence that created an error signal. Whatever force is pushing the system away from its set point must be “negated.” In our thermostat analogy, an air temperature below the set point causes the furnace to be turned on, which then reverses the direction of change in the air temperature.

negative feedback In regulatory systems, information that decreases a regulatory response, returning the system to the set point. (Contrast with positive feedback.)

Although not as common as negative feedback, **positive feedback** also exists in physiological systems. Rather than returning a system to a set point, positive feedback amplifies a response (i.e., it increases the deviation from the set point). An example is sexual behavior, in which a little stimulation causes more behavior, which causes more stimulation, and so on. Positive feedback responses tend to reach a limit and terminate rapidly. The birth process is a good example. Contractions of the uterus push the baby into the birth canal, and stretching of the birth canal stimulates more and stronger contractions until the baby is delivered, at which time contractions cease.

positive feedback In regulatory systems, information that amplifies a regulatory response, increasing the deviation of the system from the set point. (Contrast with negative feedback.)

Feedforward information is another feature of regulatory systems. Its function is to change the set point in anticipation of a change in conditions. The timer on a thermostat provides feedforward information by changing the system’s temperature set point, usually lowering it in the evening and raising it in the morning. Hearing the words “on your mark” before a race is feedforward information that raises your heart rate in anticipation of running. Feedforward information anticipates a change in the internal environment before that change occurs.

feedforward information In regulatory systems, information that changes the set point of the system. (Contrast with feedback.)

 Activity 39.2 System Simulation www.Life11e.com/ac39.2

39.2 recap

The internal environment provides for the needs of all the cells that make up a complex multicellular animal. Organs and organ systems control the composition of the internal environment so as to maintain homeostasis. The activities of organs and organ systems are regulated. Regulation requires information about optimal conditions (set points) and existing conditions (feedback) to create commands to effector cells and organs.

learning outcomes

You should be able to:

- Explain why homeostasis of the internal environment in a multicellular animal is critical to the animal's survival.
 - Use knowledge about fluid compartments in the human body to perform analyses.
 - Differentiate between negative feedback, positive feedback, and feedforward control mechanisms.
-

1. Why is maintenance of the internal environment considered to be the primary focus of physiology?
 2. Explain the differences between negative and positive feedback and feedforward control mechanisms.
 3. Based on your body mass, estimate how much water is in your body. What is your intracellular fluid volume, your extracellular fluid volume, and your blood plasma volume?
-

Principles of control and regulation help organize our thinking about physiological systems. Once we understand how a system works, we can then ask how it is regulated. [Part Nine](#) of this book describes various physiological systems, how they function, and how they are regulated. We begin by extending our example of a house thermoregulatory system to that of the mammalian body.

39.3 Biological Processes Are Temperature-Sensitive

Temperatures of environments where organisms live vary enormously, from the boiling hot springs of Yellowstone National Park to the interior of Antarctica, where the temperature can fall below -80°C . But in general, cells can function over only a narrow range of temperatures. The evolution of thermoregulatory adaptations enables maintenance of suitable thermal conditions in the internal environment.

focus your learning

Cells can survive only within a small range of the temperatures that occur on Earth.

Q_{10} values are measures of temperature sensitivity of biochemical reactions or physiological processes.

Temperature acclimatization allows animals to shift their metabolic rates as they experience seasonal changes in external temperatures.

Metabolic acclimatization enables animals to adapt to seasonal temperature changes.

Temperature affects living systems

If cells cool below the freezing point of their body fluids, ice crystals form and damage cell structures. Some animals have adaptations, such as antifreeze molecules in their blood that help them resist freezing; others can survive freezing (**Figure 39.6**). Generally, however, cells must remain above freezing to stay alive. The upper temperature limit for survival in most cells is about 45°C because of **protein denaturation**. Some specialized algae, however, can grow in hot springs at 70°C , and some archaea live at near 100°C .

protein (pro' teen) [Gk. *protos*: first] Long-chain polymer of amino acids with twenty different common side chains. Occurs with its polymer chain extended in fibrous proteins, or coiled into a compact macromolecule in enzymes and other globular proteins. The component amino acids are encoded in the triplets of messenger RNA, and proteins are the products of genes.

Figure 39.6 Frozen Frogs Wood frogs (*Rana sylvatica*) live in the northeastern United States, across most of Canada, and up into northern Alaska. They freeze solid in the winter and survive. During the fall and early winter, urea and glucose accumulate in the frogs' cells and act as intracellular cryoprotectants (like antifreeze in your car radiator). Also, much intracellular water is redistributed to the extracellular fluid, which can freeze without damaging cells.

Although the survival limits for most cells fall in the range of 0°C-40°C, most species have much narrower thermal limits for optimal function. To stay within those limits in spite of environmental conditions, animals have [thermoregulatory adaptations](#) that enable them to tolerate extreme conditions or to control their body temperature in spite of environmental conditions. These adaptations may determine the thermal tolerances of species and thereby determine their geographic ranges. When environments change rapidly, as is happening globally at present, animals may find themselves in situations that exceed their thermal tolerances. A good example is the reef-building corals discussed in the opening of [Chapter 1](#).

thermoregulatory adaptations Physiological and behavioral mechanisms for altering the heat content of the body.

Q₁₀ is a measure of temperature sensitivity

Even between 0°C and 40°C, changes in body temperature create problems for animals. Most [*biochemical reactions](#) and the physiological processes they are involved in are temperature-sensitive, going faster at higher temperatures. The temperature sensitivity of a reaction or process can be described in terms of **Q₁₀**, a factor calculated by dividing the rate of a process or reaction at a certain temperature, R_T , by the rate of that same process or reaction at a temperature 10°C lower, R_{T-10} :

$$Q_{10} = \frac{R_T}{R_{T-10}}$$

Q_{10} can be measured for a simple biochemical reaction or for a complex physiological process, such as rate of oxygen consumption. If a reaction or process is not temperature-sensitive, it has a Q_{10} of 1. Most biological Q_{10} values are between 2 and 3. A Q_{10} of 2 means that the reaction rate doubles as temperature increases by 10 °C, and a Q_{10} of 3 indicates a tripling of the rate over a 10 °C temperature range ([Figure 39.7](#)).

Figure 39.7 Q_{10} and Reaction Rate The larger the Q_{10} of a reaction or process, the faster its rate rises in response to an increase in temperature.

Notice that the Q_{10} values (except for $Q_{10} = 1$) plotted in Figure 39.7 produce curves rather than straight lines. This is because temperature increases in additive intervals (10, 20, 30, etc.) but reaction rates increase in a multiplicative fashion (2, 4, 8, 16, 32, etc.). Such curvilinear plots are common in biological data.

Changes in body temperature can disrupt an animal's physiology because not all of the biochemical reactions that constitute the metabolism of an animal have the same Q_{10} . These biochemical reactions are linked together in complex networks: the products of one reaction are the reactants for other reactions. Because different reactions have different Q_{10} 's, changes in tissue temperature will shift the rates of some reactions more than others, disrupting the overall network. Therefore, to maintain homeostasis, organisms compensate for or prevent changes in body temperature.

Animals acclimatize to seasonal temperatures

The body temperatures of some animals (especially aquatic animals) are coupled to environmental temperature. The body temperature of a fish in a pond, for example, is the same as the water temperature, which might range from 4°C in winter to 24°C in summer. If we bring that fish into the laboratory in the summer and measure the rates of any of its physiological or biochemical processes such as oxygen consumption, we will demonstrate a Q_{10} relationship. On the basis of the Q_{10} relationship, we would predict that the fish's oxygen consumption—a measure of its metabolic rate—would be lower in the winter pond because the water temperature is lower. However, if we bring that fish back into the laboratory in the winter and measure its metabolic rate at winter pond temperature, we find that rate to be higher than we predicted. The fish's biochemistry and physiology will have **acclimatized** to the seasonal change in water temperature so that it can remain active at winter temperatures. What could be the mechanism of this acclimatization? Many organisms express multiple forms of enzymes

([isozymes](#)) that have different temperature optima. In winter, organisms express the forms that show maximum substrate affinity at low temperatures, and in summer they express the forms that have maximum substrate affinity at high temperature. Another mechanism of temperature acclimatization is a change in the composition of cell membranes designed to maintain optimum fluidity despite changes in temperature (see [Key Concept 6.1](#)). Acclimatization in animals essentially means that their metabolic functions are less sensitive to long-term changes in their environment than to short-term changes.

acclimation Refers to increased tolerance for environmental extremes (e.g., extreme cold) after prior exposure to them.

isozymes Enzymes of an organism that have somewhat different amino acid sequences but catalyze the same reaction.

Small changes in temperature can have large physiological effects

The story opening this chapter described a world-class marathon runner failing to finish an important race because of heat stress. As many of us have experienced, our ability to do hard work is reduced when we get overheated. Because high tissue temperatures can damage cells, shutting off a muscle's ability to do work may serve a protective function.

▶ **investigatinglife** Can the Work Capacity of Muscle Be Increased by Extracting Heat from the Palms of the Hands?

experiment

Original Paper: Grahn, D. A., V. H. Cao, C. M. Nguyen, M. T. Liu and H. C. Heller. 2012. Work volume and strength training responses to resistive exercise improve with periodic heat extraction from the palm. *Journal of Strength and Conditioning Research* 26(9): 2558–2569.

At the beginning of the chapter you learned that mammals dissipate excess heat through their non-hairy skin areas. Those skin areas are small, but they have special high-volume blood vessels that transfer heat from the body core to the skin. Humans have these same blood vessel adaptations. In this experiment, heat was extracted from the palm of a hand, and muscle work capacity was measured.

HYPOTHESIS ▶ Extracting excess heat from the body will increase the capacity of muscles to do work.

METHOD

1. Recruit seventeen healthy recreational athletes between the ages of 19 and 23 years old.
2. Instruct subjects in proper bench press technique, and determine each subject's 1 repetition maximum (the maximum weight they could lift once).
3. Divide subjects into two groups (controls with no cooling and treatment with palmar cooling). Have each group complete 5 trials of 6 sets of bench presses, until muscle failure, with the weight set to 50% of the subject's 1 repetition maximum. Between sets allow subjects to rest for 3 minutes, with the experimental group receiving palmar cooling and the control group receiving no cooling. Separate trials by at least 3 days. Record the total numbers of bench presses per trial.
4. Repeat the experiment with control and treatment groups switched.

RESULTS

Only results for first and last trials of each experiment are shown in the table.

CONCLUSION ▶ By working through the work with the data exercise, you will be able to conclude whether the hypothesis is supported or not supported by this experiment.

investigatinglife work with the data follows on next page.

Subject	Number of bench presses			
	Experiment 1		Experiment 2	
	First trial	Last trial	First trial	Last trial
	Control group (no cooling)		Treatment group (palmar cooling)	
1	34	46	45	50
2	50	62	58	74
3	66	69	69	73
4	53	68	80	90
5	58	73	79	107
6	61	63	67	77
7	37	38	43	76
8	50	53	56	72
9	76	72	76	98
	Treatment group		Control group	
10	66	92	89	96
11	87	97	89	94
12	70	91	80	87
13	65	86	71	99
14	57	90	84	106
15	61	87	88	107
16	45	69	75	89
17	49	73	74	75

This experiment involves a simple outcome measure: number of bench presses in 6 sets done to muscle failure. The experimental manipulation is heat extraction from a palm between sets. The control condition is an equivalent period of rest between sets without palmar cooling. The main question is whether there is a difference in the work volume when cooled versus when not cooled. However, there are some complicating factors: (1) the subjects varied considerably in their initial work capacity, and (2) since the treatments were sequential there could be an order effect. To minimize the order effect, the treatments were randomized as to palmar cooling or no cooling. Your analysis must first standardize the data, then test for an order effect, and finally test for a treatment effect.

How can you standardize the data? Because the subjects began the experiment at different ability levels, the absolute increase in repetitions cannot be used as a comparative outcome measure. An increase of 5 repetitions is more impressive for a subject who began at 25 than for one who began at 50—a 20 percent increase in contrast

to a 10 percent increase. For each individual and each treatment it is necessary to convert the raw data to percent increase.

How can you test for a treatment effect? Each subject was cooled in one treatment and not cooled in the other treatment. To see if there is a difference in the percent increase due to palmar cooling, you can average the percent increases for all subjects in their cooling treatments and for all subjects in their control treatments. Using a paired *t*-test, you can assess whether palmar cooling had a significant effect on the outcome.

QUESTIONS▶

1. Because this experiment involved repetitions of a physical activity, you would expect there to be a conditioning effect whether the subjects were cooled or not, and you might expect the improvements to be greater in the second treatment than in the first. To test for an order effect, compare the percent increases for all subjects in treatment 1 to the percent increases for all subjects in treatment 2. For statistical analysis use a paired *t*-test (see [Appendix B](#)). What do you conclude about a possible order effect in your collection of data?
2. Each subject was cooled in one treatment and not cooled in the other treatment. To see if there is a difference in the percent increase due to palmar cooling, average the percent increases for all subjects in their cooling treatments and for all subjects in their control treatments. Using a paired *t*-test, you can assess whether palmar cooling had a significant effect on the outcome. What do you conclude about a treatment effect in your experimental results?
3. Is the hypothesis supported or disproven? Explain.

A similar **work with the data** exercise may be assigned in **LaunchPad**.

Pyruvate kinase is an enzyme critical for production of ATP in muscles; it catalyzes the last step in glycolysis, producing pyruvate that can enter the mitochondria and be metabolized to produce ATP (see [Figure 9.12](#)). Without ATP, muscles fatigue. Muscle pyruvate kinase inactivates around 40°C, which shuts off muscle function and thereby prevents thermal damage to the muscle. The thermal inactivation of muscle pyruvate kinase is probably a protective adaptation to prevent thermal damage to the muscle. You may thus wonder, if we could facilitate the extraction of heat from muscle, could we increase its capacity to do work? We consider this question in **Investigating Life: Can the Work Capacity of Muscle Be Increased by Extracting Heat from the Palms of the Hands?**

39.3 recap

Cells can survive only within a narrow range of temperatures, but even changes within that range can be disruptive because different physiological processes have different temperature sensitivities.

learning outcomes

You should be able to:

- Explain why animals' body temperatures must be maintained within narrow ranges.
- Plot a given Q_{10} value for a biochemical process.
- Explain how isozymes may be involved in seasonal temperature acclimatization.

1. Explain how fluctuations in body temperature can disrupt complex physiological processes.

2. Plot a $Q_{10} = 2.5$ curve for a physiological process.
3. What characteristic of isozymes might explain their role in metabolic seasonal temperature acclimatization?

Now that you know how animals are affected by temperature, we next take a look at the adaptations that allow animals to survive wide ranges of thermal environments and wide ranges of metabolic activities.

***connect the concepts** Protein denaturation by heat is due to effects on secondary and tertiary structure of the protein as described in [Key Concept 3.2](#).

***connect the concepts** As discussed in [Key Concept 8.5](#), increases in temperature increase reaction rates because reactant molecules have more kinetic energy. Enzymes that control rates of biochemical reactions in metabolic pathways are influenced by temperature as well.

39.4 Body Temperature Depends on the Balance between Heat In and Heat Out of the Body

Body temperature is a measure of the heat content of the body. Animals produce heat internally through their metabolism, and they continuously exchange heat with their environment. The balance between heat gain and heat loss determines the animal's body temperature. Thermoregulatory adaptations enable animals to modulate the various paths of heat exchange between themselves and their environment.

focus your learning

Endotherms can increase metabolic heat production to balance increased heat loss to the environment, whereas ectotherms rely largely on behavior to control their heat exchange with the environment.

The four avenues of heat exchange between an animal and its environment are radiation, convection, conduction, and evaporation.

A countercurrent heat exchange system in some highly active fishes conserves heat generated by muscle activity.

Animals can be classified by their thermoregulatory characteristics

One way of classifying animals is according to the constancy of their body temperature. Animals that maintain a constant body temperature are called [homeotherms](#), and animals that experience a fluctuating body temperature are called [poikilotherms](#). Another classification is based on the source of heat that predominantly determines body temperature. [Endotherms](#) such as birds and mammals have the ability to vary their metabolic heat production to compensate for the loss of heat to the environment. Ectotherms such as invertebrates, fishes, amphibians, and non-avian reptiles are largely dependent on environmental sources of heat. We use the terminology of ectotherm and endotherm in this book, but no classification scheme is perfect. Many ectotherms can generate considerable internal heat to raise their body temperature, and endotherms that hibernate can periodically appear to give up the ability to generate internal heat. To accommodate these departures from a strict dichotomy, we add the term [heterotherms](#)—organisms that act like ectotherms some of the time and like endotherms at other times.

homeotherms Animals that regulate their body temperatures within a narrow range when confronted with a much greater range of environmental temperatures.

poikilotherms Animals whose body temperatures are largely dependent on environmental temperature.

endotherm [Gk. *endo*: within + *thermos*: heat] An animal that can control its body temperature by the expenditure of its own metabolic energy. (Contrast with ectotherm.)

heterotherm An animal that regulates its body temperature at a constant level at some times but not others, such as a hibernator.

Endotherms produce substantial amounts of metabolic heat

***Transfers of energy** in biological systems are inefficient. In both ectotherms and endotherms, in every transfer of energy—from food molecules to ATP, from ATP to biological work—some of the energy is lost as heat. Working muscles produce heat, as do all of the metabolic activities of all tissues.

Why do endotherms produce more heat than ectotherms? The surprising answer is that the cells of endotherms are less efficient at using energy than are the cells of ectotherms. The cells of endotherms are more “leaky” to ions than are the cells of ectotherms. Therefore Na^+ ions are constantly diffusing into the cells, and K^+ ions are constantly diffusing out. Even an endotherm at rest must spend considerable amounts of energy to transport Na^+ out of the cells and transport K^+ back in. Because of their constant need to actively transport ions, endotherms expend more energy than do ectotherms just to maintain the ion concentration gradients across their cell membranes. This situation is analogous to a leaky boat: the faster water comes in (i.e., the faster ions diffuse down their concentration gradients), the more metabolic energy has to be expended to bail the water out (i.e., pump ions back up their concentration gradients). Since endotherms expend more energy than ectotherms do to maintain ion concentration gradients, they produce more internal heat.

We can speculate that a mutation resulting in seemingly faulty or leaky ion channels may underlie the evolution of endothermy. Such a mutation in a small ectotherm would have increased its energy expenditure and therefore its heat production. Increased heat production would have enabled the animal to be active earlier in the morning or for a longer time after sunset. Being active in twilight, and eventually at night, would open up a new world of ecological opportunities—a world in which there was less competition from similar-sized ectotherms and less danger of predation.

Two major differences between endotherms and ectotherms are (1) their resting metabolic rates—the sum total of all energy expenditures in their bodies when at rest—and (2) their responses to changes in environmental temperature.

Ectotherms and endotherms respond differently to changes in environmental temperature

How do similar-sized ectotherms and endotherms respond to changes in environmental temperature? Let's compare a lizard and a mouse. We put each animal in a closed chamber and measure its body temperature and its resting metabolic rate as we change the temperature of the chamber from 40°C to 0°C. The body temperature of the lizard equilibrates with that of the chamber, whereas the body temperature of the mouse remains stable over most of this range (**Figure 39.8A**). The metabolic rate of the lizard (already much lower than that of the mouse when both are at warm temperatures) decreases as the temperature drops (**Figure 39.8B**). In contrast, the mouse's metabolic rate increases as the chamber temperature falls below 25°C. This increase in metabolism produces enough heat to prevent the mouse's body temperature from falling. In other words, the mouse can regulate its body temperature by increasing its metabolic rate and thereby maintain its physiological functions at an optimal level; the lizard cannot.

(A)

Figure 39.8 Ectotherms and Endotherms React Differently to Environmental Temperatures (A) At the same environmental temperature, an ectotherm and an endotherm of approximately the same body size (here, a lizard and a mouse) have different body temperatures. **(B)** The metabolic rates of the lizard and mouse react in opposite ways to cooler temperatures.

Q: In the plot of body temperature versus environmental temperature, why does the mouse curve fall on the far left side and rise on the far right side? In the plot of metabolic rate versus environmental temperature, why does the mouse's metabolic rate rise at higher temperatures?

This experiment might lead us to conclude that the ectotherm cannot regulate its body temperature, but observations of the lizard in nature do not support this conclusion. In nature, the lizard can regulate its body temperature quite well, although it does so by behavioral mechanisms rather than by altering its internal metabolic heat production. Air temperature in the desert can fluctuate by 40°C or more in a few hours; the lizard, however, can limit its variation in body temperature and even maintain a fairly stable body temperature by using behavior to alter its heat exchange with the environment. Its behavioral strategies include spending time in a burrow, basking in the sun, seeking shade, climbing vegetation, and changing its orientation with respect to the sun.

Endotherms also use behavior as a first line of defense against thermal stress. They select the most comfortable thermal environment possible. They change posture or their orientation to the sun, move between sun and shade, and move between still air and moving air. Examples of more complex thermoregulatory behaviors include nest construction and social behaviors such as huddling. Humans put on or remove clothing and burn fossil fuels to generate the energy to heat or cool buildings.

Energy budgets reflect adaptations for regulating body temperature

Both ectotherms and endotherms influence their body temperatures by altering four avenues of heat exchange between their bodies and the environment (**Figure 39.9**):

Figure 39.9 Animals Exchange Heat with the Environment An animal's body temperature is determined by the balance between internal heat production and four avenues of heat exchange with the environment: radiation, convection, conduction, and evaporation.

- **Radiation** Heat moves from warmer objects to cooler ones via the exchange of infrared radiation (what you feel when you stand in front of a fire).

radiation The transfer of heat from warmer objects to cooler ones via the exchange of infrared radiation. (See also electromagnetic radiation, evolutionary radiation.)

- **Convection** Heat exchanges with a surrounding medium such as air or water that flows over a surface (the wind-chill factor).

convection The transfer of heat to or from a surface via a moving stream of air or fluid.

- **Conduction** Heat flows directly between two objects at different temperatures when they come into contact (e.g., an icepack on a sprained ankle).

conduction The transfer of heat from one object to another through direct contact.

- **Evaporation** Heat is transferred away from a surface when water evaporates on that surface (the effect of sweating).

evaporation The transition of water from the liquid to the gaseous phase.

The total balance of heat production and heat exchange can be expressed as an **energy budget**, based on the simple fact that if the body temperature of an animal is to remain constant, the heat entering the animal must equal the heat leaving it. The heat coming in is usually from metabolism and radiation (R_{abs} , for radiation absorbed). Heat leaves the body via the four mechanisms listed above—radiation emitted (R_{out}), convection, conduction, and evaporation. The energy budget takes the mathematical form

energy budget A quantitative description of all paths of energy exchange between an animal and its environment.

$$\underbrace{\text{heat}_{\text{in}}}_{\text{metabolism} + R_{\text{abs}}} = \underbrace{\text{heat}_{\text{out}}}_{R_{\text{out}} + \text{convection} + \text{conduction} + \text{evaporation}}$$

The energy budget is a useful concept because any adaptation that influences the ability of an animal to control its temperature must affect one or more components of the energy budget. The energy budget gives us the ability to quantify and compare the thermal adaptations of animals. One interesting observation is that all of the components on the right side of the energy budget equation — that is, the heat-loss side—depend on the surface temperature of the animal. In fact, if the environmental temperature is above skin surface temperature, convection and conduction are avenues of heat gain rather than loss. One way surface temperature can be controlled is by altering the flow of blood to the skin.

Both ectotherms and endotherms control blood flow to the skin

Heat is mostly moved around the internal environment by blood flow. Heat produced in muscles during exercise is transported out of the muscle and to the heart in the blood. That heat is then distributed around the body by the blood, raising body temperature. Blood flow to the skin enables internal heat to be lost to the environment through radiation, convection, conduction, and evaporation, thus bringing the body temperature back toward normal. When body temperature is too low or the environment is too cold, the blood vessels supplying the skin constrict, reducing heat loss to the environment.

The ability to control blood flow to the skin can be an important adaptation for an ectotherm such as the marine iguana (a reptile) of the Galápagos archipelago (**Figure 39.10**). The Galápagos are volcanic islands that lie on the equator but are bathed by cold ocean currents. Iguanas bask on hot black lava rocks on the shore, and periodically enter the cold ocean water

to feed on seaweed. While the iguanas are feeding, they lose heat to the cold ocean water. This cooling lowers their metabolism, making them slower, more vulnerable to predators, and incapable of efficient digestion. The iguanas therefore alternate between feeding in the cold seawater and basking on the hot rocks. It is advantageous for iguanas to retain body heat as long as possible while swimming and to warm up as fast as possible when basking. They accomplish these results by changing their heart rate and thus the rate of blood flow to their skin and around their bodies.

Figure 39.10 Some Ectotherms Regulate Blood Flow to the Skin Galápagos marine iguanas control blood flow to the skin to alter their heating and cooling rates.

What about furred mammals? Fur acts as insulation to keep body heat in, making it possible for mammals to function in cold environments. When they are active, however, mammals must get rid of excess heat, and it does little good to transport that heat to the skin under the fur. Thus, as mentioned at the opening of this chapter, mammals have specialized blood vessels for transporting heat to their hairless skin surfaces. Heat loss from these areas is tightly controlled by the opening and closing of these blood vessels. When you are cold, the blood flow to your

hands and feet decreases and they feel cold, but when you exercise, the blood vessels serving these skin areas dilate increasing the blood flow and therefore the heat dissipation.

Media Clip 39.1 Thermoregulation in Animals www.Life11e.com/mc39.1

Some fishes conserve metabolic heat

The muscles of active fishes produce substantial amounts of metabolic heat, but most fishes cannot retain that heat. Blood pumped from the fish heart goes directly to the gills, where it comes very close to the surrounding water to exchange oxygen and carbon dioxide. Any heat the blood picks up from metabolically active muscles is lost to the water flowing across its gills. It is therefore surprising that some large, rapidly swimming fishes, such as giant bluefin tuna (see [Figure 1.15A](#)) and great white sharks, can maintain swimming muscle temperatures 10°C-15°C higher than the surrounding water. The heat comes from their powerful swimming muscles, and the ability of these “hot” fishes to conserve that heat is based on the remarkable arrangement of their blood vessels.

In the typical (“cold”) fish circulatory system, oxygenated blood from the gills collects in a large blood vessel, the aorta, that runs through the center of the fish, distributing blood to all organs and muscles ([Figure 39.11A](#)). “Hot” fishes have a small aorta, and most of their oxygenated blood is transported in large side vessels just under the skin ([Figure 39.11B](#)). The cold blood leaving the gills is therefore kept close to the surface of the “hot” fishes as it flows posteriorly to the swim-ming muscles. The cold blood flows into the muscle mass through small vessels branching off the large side vessels. These many small vessels run parallel to the vessels carrying warm blood from the swimming muscles back toward the heart. Because the vessels carrying the cold blood into the muscles are in close contact with the vessels carrying warm blood out of the muscles, heat flows from the warm to the cold blood by conduction. Therefore the heat produced by the active muscles is retained in the muscle mass.

Figure 39.11 “Cold” and “Hot” Fishes (A) Blood flowing through fish gills comes into temperature equilibrium with water temperature. In most fish species, this oxygenated but cool blood flows through a large dorsal aorta to the rest of the body. Thus it is an internal cooling source. (B) The anatomy of “hot” fish species circulates most of the cool, oxygenated blood to the body through large peripheral arteries rather than through a central aorta. As this cool arterial blood flows into the swimming

muscle, it is warmed by heat being carried out of the swimming muscle by the veins. Thus, the heat generated by the swimming muscles is conserved in the muscle mass. **(C)** The close, parallel arrangement of the arteries carrying blood into the muscles and the veins carrying blood out of the muscle makes efficient countercurrent heat exchange possible.

Because heat is exchanged between blood vessels carrying blood in opposite directions, this adaptation is called **countercurrent heat exchange** (**Figure 39.11C**). By keeping heat within the muscles, these fishes can maintain an internal body temperature considerably higher than the water temperature. Each 10°C rise in muscle temperature increases the fish's power output almost threefold, giving it a faster and more powerful swimming capability.

countercurrent heat exchange In “hot” fishes, an adaptation of the circulatory system such that arterial blood flowing into the muscles is warmed by venous blood flowing out of the muscles, thereby conserving body heat by countercurrent exchange.

Some ectotherms regulate metabolic heat production

By definition, ectotherms are largely dependent on environmental sources of heat for thermoregulation, but some ectotherms raise their body temperatures by producing metabolic heat. For example, the powerful flight muscles of many insects must reach 35°C-40°C before the insects can fly, and they must maintain these high temperatures during flight. Such insects warm up to fly by contracting their flight muscles isometrically in a manner similar to shivering in mammals. The heat-producing ability of insect muscle can be quite remarkable. An impressive case is a species of scarab beetle that lives mostly underground in mountains north of Los Angeles, California. These beetles come aboveground to mate, with the males flying in search of females. They undertake this mating ritual only at night, in winter, during snowstorms.

Honey bees regulate temperature as a group. They live in large colonies consisting mostly of female worker bees that maintain the hive and rear the larval offspring of the single queen bee. During winter, worker bees cluster around the brood (eggs and larvae). They adjust their individual metabolic heat production and density of clustering so that the brood temperature remains remarkably constant, at about 34 °C, even as the outside air temperature drops below freezing.

39.4 recap

Endotherms use metabolic heat production to maintain constant high body temperatures. Body temperatures of ectotherms are more dependent on environmental heat sources. Both ectotherms and endotherms use behavior to control their body temperature. Heat exchange between an animal and its environment occurs via radiation, convection, conduction, and evaporation, all of which depend on body surface temperature. Some ectotherms use metabolic heat production episodically to raise body temperature.

learning outcomes

You should be able to:

- Explain responses to environmental temperature by an ectotherm, an endotherm, and a heterotherm.
- Describe the paths of heat exchange between an animal and its environment.

- Explain the principle of countercurrent heat exchange.
-

1. Why is the body temperature of an ectotherm that is exposed to variations in environmental temperature more constant in nature than in the laboratory?
2. For each path of heat exchange, what determines whether heat is gained or lost by the animal?
3. Compared to most fishes, explain the circulatory system adaptations that enable “hot” fishes to raise the temperature of their swimming muscles.

Endotherms respond to changes in environmental temperature by changing their rates of metabolic heat production. They also have other adaptations for controlling their rates of heat exchange with their environments. How do they regulate these various avenues of heat exchange to achieve a constant internal body temperature?

***connect the concepts** As discussed in [Key Concept 8.1](#), transfers of energy are governed by the first and second laws of thermodynamics, which explain why heat is always a by-product of metabolism.

39.5 Body Temperature Is Regulated through Adaptations for Heat Production and Heat Loss

As explained in [Key Concept 39.2](#), there is a difference between control and regulation. Think of driving your car. You control the speed of the car with the accelerator and the brake, but you regulate the speed of your car by comparing the speed limit (set point) with your speedometer (feedback) to generate command signals to your foot that is operating the accelerator and brake. For understanding how body temperature is regulated, you must understand the adaptations for heat production and heat loss, how they are controlled, and what information is used to modulate the control signals to achieve a regulated body temperature.

focus your learning

The basal metabolic rate (BMR) of an endotherm is the lowest metabolic rate necessary for biochemical and physiological processes of a resting animal.

Endotherms produce and conserve metabolic heat to offset heat loss in cold environments.

Mammalian body temperature is controlled by a regulatory center in the hypothalamus that uses hypothalamic temperature as the feedback information.

Basal heat production rates of endotherms correlate with body size

Physiologists can determine an animal's metabolic rate and therefore its rate of heat production by measuring its consumption of O_2 or production of CO_2 . Within a narrow range of environmental temperatures, called the [thermoneutral zone](#) (see [Figure 39.9B](#)), the metabolic rates of endotherms (birds and mammals) are at low levels and independent of environmental temperature. The metabolic rate of a resting endotherm at a temperature within its thermoneutral zone is its [basal metabolic rate \(BMR\)](#). BMR is usually measured in animals that are quiet but awake and not using energy for digestion, reproduction, or growth. Thus BMR is the rate at which a resting animal is consuming just enough energy to carry out its minimal body functions.

thermoneutral zone [Gk. *thermos*: temperature] The range of temperatures over which an endotherm does not have to expend extra energy to thermoregulate.

basal metabolic rate (BMR) The minimum rate of energy turnover in an awake (but resting) bird or mammal that is not expending energy for thermoregulation.

As you might expect, the BMR of an elephant is greater than that of a mouse. After all, the elephant is more than 100,000 times larger than the mouse. However, the BMR of the elephant is only about 7,000 times greater than that of the mouse. That means that a gram of mouse tissue uses energy at a rate 15 times greater than a gram of elephant tissue ([Figure 39.12](#)). Across all of the endotherms, BMR per gram of tissue increases as animals get smaller.

Figure 39.12 The Mouse-to-Elephant Curve On a weight- specific basis, the basal metabolic rate of small endotherms is much greater than that of larger endotherms. This classic illustration, originally published in the 1930s, plots O₂ consumption per kilogram of body mass (a measure of metabolic rate) against a logarithmic plot of body mass.

Q: Only 9 species are shown on this curve, but hundreds of species from the tropics to the arctic fit on this curve as well. What does that fact allow you to conclude about whether or not basal metabolic rate is an adaptation to climate?

Why should this disproportionate difference exist? There are several possible reasons. As animals get bigger, they have a smaller surface area-to-volume ratio (see [Figure 5.2](#)). Since heat production is related to the volume (i.e., mass) of the animal, but its capacity to dissipate heat is related to its surface area, it has been reasoned that larger animals evolved lower metabolic rates to avoid overheating. However, this explanation alone is insufficient because the relationship between body mass and basal metabolic rate holds for even very small organisms and for ectotherms, in which overheating is not a problem. Other hypotheses have also been proposed. For example, a larger animal has a greater proportion of support tissues (e.g., skin and bone), which are not as metabolically active as other tissue types. The real explanation is probably a mixture of different factors, but the relationship holds over a very broad range of species.

For an endotherm, a metabolic rate versus environmental temperature curve represents the integrated response of all the animal's thermoregulatory adaptations (**Figure 39.13**). The thermoneutral zone is bounded by a [lower critical temperature and an upper critical temperature](#). When the environmental temperature is within the thermoneutral zone, an endotherm's thermoregulatory responses do not require much energy and could be considered passive; such responses include changing posture, fluffing fur or feathers, and altering blood flow to the skin. Outside its thermoneutral zone, however, an endotherm's thermoregulatory responses are active and require metabolic energy.

lower critical temperature The environmental temperature at which a resting endotherm must increase its metabolic rate to avoid a drop in its body temperature.

Figure 39.13 Environmental Temperature and Mammalian Metabolic Rates A plot of an endotherm's metabolic rate versus environmental temperature represents the integrated response of all of its thermoregulatory mechanisms. Outside the thermoneutral zone, maintaining a constant body temperature requires expending energy. Outside extreme limits (0°C and 40°C in this instance), the animal cannot maintain its body temperature and dies.

Endotherms respond to cold by producing heat and adapt to cold by reducing heat loss

When environmental temperatures fall below the lower critical temperature, endotherms increase metabolic heat production to compensate for heat loss. Mammals can accomplish this by shivering and/or nonshivering heat production. Birds use only shivering heat production. Shivering uses the contractions of skeletal muscles to convert ATP to ADP, with the energy from this process released as heat. Shivering muscles pull against each other so that little movement other than a tremor results. "Shivering heat production" is perhaps too narrow a term, however; increased muscle tone and increased body movements also contribute to increased heat production in cold environments.

Most nonshivering heat production occurs in specialized adipose tissue called **brown fat**. This tissue looks brown because of its abundant mitochondria and rich blood supply. In brown fat cells, a protein called **thermogenin** uncouples proton movement from ATP production, allowing protons to leak across the inner mitochondrial membrane rather than having to pass through the ATP synthase and generate ATP (review the discussion of brown fat and the chemiosmotic mechanism in [Key Concept 9.3](#)). As a result, metabolic fuels are consumed without producing

ATP, but heat is still released.

brown fat In mammals, fat tissue that is specialized to produce heat. It has many mitochondria and capillaries, and a protein that uncouples oxidative phosphorylation.

thermogenin Also called Uncoupling Protein 1 (UPC1). A protein in the mitochondria of brown fat that uncouples oxidative phosphorylation.

Pads of brown fat are found in newborns of many mammalian species. Brown fat is also commonly found in adult mammals that are small and acclimatized to cold, and in mammals that hibernate. Recently it has been discovered that adult humans have small amounts of brown fat distributed around the body and that its metabolic activity is stimulated by cold exposure. One study found less brown fat activity in obese than in lean individuals, leading to the hypothesis that individual differences in propensity for weight gain may be related to the amount of brown fat in an individual, as described in the opening stories of [Chapters 9](#) and [40](#).

In addition to their ability to produce heat, endotherms that live in cold climates have evolved adaptations to reduce their heat loss. Heat is lost from the body surface, and cold-climate species have anatomical adaptations that give them smaller surface area-to-volume ratios than their warm-climate relatives ([Figure 39.14](#)). These adaptations include rounder body shapes and shorter appendages.

Figure 39.14 Adaptations to Cold and Hot Climates (A) The antelope jackrabbit is found in the Sonoran Desert of Arizona. Its large ears serve as heat exchangers,

passing heat from the animal's blood to the surrounding air. **(B)** The thick fur of the Arctic hare provides insulation, and its rounded body shape lowers its surface area-to-volume ratio. The ears and extremities are smaller than those of its warm-climate relatives, so less heat is lost to the environment.

The most common and important means of decreasing heat loss is to increase thermal insulation. Animals adapted to cold climates have much thicker layers of fur, feathers, and/or fat than do their warm-climate relatives. Fur and feathers are good insulators because they trap a layer of still, warm air close to the skin surface. If that air is displaced by water, insulation is drastically reduced. In many species, oil secretions spread through fur or feathers by grooming are critical for resisting wetting and maintaining a high level of insulation. In terms of the energy budget equation presented in [Key Concept 39.4](#), remember that heat exchange between the animal and its environment is a function of the animal's surface temperature. For a body area covered by fur or feathers, surface temperature is that of the outer surface of the fur or feathers.

The ability to decrease blood flow to the noninsulated skin is an important thermoregulatory adaptation for cold-climate endotherms. Constriction of blood vessels in the skin, and especially in the appendages, greatly improves an animal's ability to conserve heat. Countercurrent heat exchange like that you saw in "hot" fishes is also an important adaptation in the appendages of endotherms. Warm blood flowing out to the paw of a wolf, the hoof of a caribou, or the foot of a bird parallels the flow of the cooler blood returning to the body core. Heat is transferred from the outgoing to the returning blood, thus retaining heat in the animal's core.

Activity 39.3 Thermoregulation in an Endotherm www.Life11e.com/ac39.3

Evaporation of water can dissipate heat, but at a cost

At the upper end of the thermoneutral zone, an endotherm dissipates heat through adaptations that don't require much energy: increasing blood flow to the skin, seeking shade and cool breezes, and decreasing activity. But when the environmental temperature exceeds the upper critical temperature, these adaptations are not sufficient and overheating becomes a problem. For exercising animals (including athletes), overheating can occur even at low environmental temperatures. Large mammals, especially those in hot habitats such as elephants, rhinoceroses, and water buffaloes, have little or no insulating fur and seek out water to wallow in when the air temperature is high. Having water in contact with the skin greatly increases heat loss because the heat-absorbing capacity of water is much greater than that of air.

Evaporation from external or internal body surfaces through sweating or panting can also cool an endotherm. A gram of water absorbs about 580 calories of heat when it evaporates. If this evaporation occurs on the skin, most of the heat comes from the skin. However, sweat or saliva that falls off the body provides no cooling. Thus when the need for heat loss is greatest, water from the internal environment can be squandered with no cooling benefit. Water is heavy, so animals do not carry an excess supply of it, and many hot environments are also arid. In habitats that are both hot and dry, sweating and panting are cooling adaptations of last resort.

Sweating and panting are *active* processes that require expending metabolic energy. That is why the metabolic rate increases when the upper critical temperature is exceeded (see [Figure 39.16](#)). A sweating or panting animal is generating heat in the process of dissipating heat, which can be a losing battle.

The mammalian thermostat uses feedback information

The thermoregulatory mechanisms and adaptations of endotherms are controlled by neural regulatory systems that integrate information from environmental and internal sources and then issue commands to the effectors that alter the heat content of the body. These regulatory systems are similar in principle in birds and mammals but differ in many details. Here we focus on the nervous system thermostats of mammals.

The major thermoregulatory integrative center of mammals is at the base of the brain in a structure called the hypothalamus ([Figure 39.15](#)). The hypothalamus is a key player in many regulatory systems of vertebrates. Experiments demonstrating its role have shown that slight cooling of the hypothalamus stimulates constriction of skin blood vessels and that stronger cooling increases metabolic heat production. As a result, cooling of the hypothalamus in an unchanging, thermoneutral environment will cause body temperature to rise. Conversely, hypothalamic heating causes the overall body temperature to fall ([Figure 39.16](#)).

Figure 39.15 The Mammalian Thermostat Like the home thermostat in [Figure 39.5](#), the mammalian hypothalamus is the regulatory system that controls the body's heating and cooling mechanisms.

Figure 39.16 The Hypothalamus Regulates Body Temperature

Original Paper: Heller, H. C., Colliver, G. W., and P. Anand, 1974. CNS regulation of body temperature in euthermic hibernators. *American Journal of Physiology*. 227:576–582.

A mammal's hypothalamus was subjected directly to temperature manipulation. The body's responses to the manipulations were as expected if the hypothalamus is the mammalian "thermostat."

HYPOTHESIS▶ Heating or cooling the mammalian hypothalamus results in predictable changes in body temperature.

METHOD

1. Implant a probe into the hypothalamus of a living ground squirrel's brain. Use the probe to heat or cool the hypothalamus directly (i.e., without affecting the ambient temperature).
2. Manipulate the hypothalamic temperature T_H .

3. Measure the animal's metabolic rate and body temperature throughout the period of hypothalamic manipulation.

RESULTS

- 1 When the hypothalamus was cooled, metabolic heat production increased and the animal's body temperature rose.
- 2 When the hypothalamus was heated, the squirrel's metabolic rate and body temperature fell.

CONCLUSION▶ The ground squirrel's hypothalamus acts as a thermostat. When cooled, it activates metabolic heat production; when warmed, it suppresses metabolic heat production and favors heat loss.

In mammals, the temperature of the hypothalamus itself is the major feedback signal. The hypothalamus generates set points for various thermoregulatory responses. When the temperature of the hypothalamus exceeds or drops below those set points, thermoregulatory responses are activated to reverse the direction of temperature change (see Figure 39.15). The system integrates other sources of information in addition to hypothalamic temperature. For example, temperature sensors in the skin register environmental temperature. A change in skin temperature is feedforward information that shifts hypothalamic set points; the set point for metabolic heat production is higher when the skin is cold and lower when the skin is warm.

Hypothalamic set points are higher during wakefulness than during sleep, and they are higher during the active part of the daily cycle than the inactive part, even if the animal is awake at both times. Even when an endotherm is kept under constant environmental conditions, its body temperature displays a daily cycle of changes in set point. This kind of cycle, a ***circadian rhythm**, is controlled by an internal biological clock.

▶ Animation 39.1 The Hypothalamus www.Life11e.com/a39.1

Some animals conserve energy by turning down the thermostat

Hypothermia is a below-normal body temperature. It can result from starvation (lack of metabolic fuel), exposure to extreme cold, serious illness, or anesthesia. In each of these cases, the drop in body temperature is *unregulated*. However, many birds and mammals undergo *regulated* hypothermia to survive periods of cold and food scarcity.

hypothermia Below-normal body temperature.

Hummingbirds, for example, are very small endotherms with a high metabolic rate, and going even a single day without food could exhaust their metabolic reserves. Hummingbirds and other small endotherms extend the period over which they can survive without food by dropping their body temperature by 10°C–20°C during the portion of day when they are normally inactive, thus lowering their metabolic rate and conserving energy. Daily bouts of regulated hypothermia are

called **daily torpor**.

daily torpor A daily reduction in metabolic rate and body temperature to conserve energy.

Regulated hypothermia that lasts for days or even weeks, during which the body temperature falls close to environmental temperature, is called **hibernation** (Figure 39.17). Many species of mammals, including bats, bears, marmots, and ground squirrels, hibernate, but only one species of bird (the common poorwill) has been shown to hibernate. The metabolic rate needed to sustain a hibernating animal may be only one-fiftieth its basal metabolic rate, and many hibernating animals maintain body temperatures close to the freezing point. Arousal from hibernation occurs when the hypothalamic set point returns to the normal level. The ability of animals to enter daily torpor or deep hibernation to reduce their thermoregulatory set point so dramatically probably evolved as an extension of the set point decrease that accompanies sleep in all mammals and birds.

hibernation [L. *hibernum*: winter] The state of inactivity of some animals during winter; marked by a drop in body temperature and metabolic rate. (Contrast with estivation.)

Figure 39.17 Hibernation Patterns in a Ground Squirrel (A) During most of the year, the ground squirrel regulates its body temperature around 37 °C. During winter months, however, these animals hibernate in underground burrows, living off stored fuel (in the form of either fat or cached food). (B) The metabolic demands for these stored fuels are decreased by bouts of torpor, during which body temperature drops close to that of the environment for long periods of time.

39.5 recap

Within the thermoneutral zone, an endotherm controls its body temperature by passive means. Above or below the thermoneutral zone, an endotherm must expend considerable metabolic energy to control body temperature. Thermoregulatory responses in mammals are regulated by the hypothalamus.

learning outcomes

You should be able to:

- Describe the thermoneutral zone and the upper and lower critical temperatures and how they relate to the basal metabolic rate of an endotherm.
- Interpret a plot of metabolic rate versus environmental temperature for an endotherm.
- Explain differences in physical features of endotherms of the same or similar species that live in climates of different temperature extremes.
- Describe how the mammalian brain thermostat uses feedback and feedforward information to regulate body temperature.
- Explain the variable features of the mammalian thermoregulatory system.

1. What determines the upper and lower boundaries of the thermoneutral zone?
2. In the metabolic rate versus ambient temperature curve for mammals shown in [Figure 39.13](#), the segment of the curve below the lower critical temperature is described by the equation $MR = K(T_b - T_a)$. In this equation, what does K stand for? Why does this equation predict that the curve it describes will meet the x axis at a temperature that equals body temperature?
3. Explain why arctic species of mammals tend to be bigger and stockier than closely related species in warmer environments.
4. What are the roles of feedforward information in the mammalian thermoregulatory system?
5. Explain why the mammalian thermoregulatory system has been described as a proportional thermostat with an adjustable set point.

investigatinglife

How can we increase heat loss from the body to protect against heat stress?

In the opening story to this chapter you saw that body temperature is a critical factor in limiting physical performance. In [Key Concept 39.4](#) you learned that body surface temperature is a critical factor in each path of heat loss. The relevant body surface temperature for furred mammals is mostly the surface of the fur. For us it is mostly the surface of our clothing. We can take off our clothes, but furred mammals cannot take off their fur. Mammals have evolved special blood vessel adaptations in their non-hairy skin that can accommodate large volumes of blood and therefore support high levels of heat loss. The experiment in Investigating Life: Can the Work Capacity of Muscle Be Increased by Extracting Heat from the Palms of the Hands? used a technology to extract large amounts of heat from the palm of one hand and showed a resulting improvement in ability to do muscular work.

How does this heat-loss adaptation, and the technology designed to amplify it, work?

Blood flows from the heart through large arteries, then through small arteries, and then through the tiny capillaries that nourish the tissues and carry away waste products of metabolism, and then into veins that carry the blood back to the heart. The circulatory adaptations of the “heat portals” in non-hairy mammalian skin are an exception to this pattern. In the non-hairy skin, gated shunts deliver arterial blood directly to veins, bypassing the capillaries. These veins in non-hairy skin form networks that can accommodate a large volume of blood when the shunts are open. Based on this knowledge, biologists at Stanford University developed the “rapid-cooling” technology used in the experiment in Investigating Life: Can the Work Capacity of Muscle Be Increased by Extracting Heat from the Palms of the Hands? The palm of the hand (non-hairy skin) is placed in contact with a cooled surface and a mild vacuum is used to pull more blood into the large, heat-exchanging blood vessels. When this device is used, body temperature rises more slowly during exercise and cools more rapidly during rest after exercise.

As expected, this rapid cooling technology greatly increased endurance for exercise in the heat, but an unexpected discovery was enhanced athletic performance. Because muscle fatigue is partly due to increased muscle temperature, enhanced cooling reduces fatigue and increases exercise capacity, which in turn can lead to conditioning gains. In one study, first-year college students in a conditioning program doubled their rate of physical conditioning when they used the cooling technology. After 6 weeks of training, some men and women in the study achieved more than 900 pushups or hundreds of pull-ups in a 45-minute workout session.

Future directions

In this chapter you learned that virtually all biological processes are affected by temperature. Therefore, if we have a new technology that can rapidly and efficiently alter the heat content of the body, we should find many applications for it. What could some of those applications be besides improving athletic performance? Consider a few medical applications. Active thermoregulatory responses such as vasoconstriction, shivering, and sweating depend on control by the nervous system, but all of these mechanisms are inactivated by anesthesia and patients can become seriously hypothermic. Their body temperatures could be stabilized by heat exchange through their natural heat portals. Some medical conditions render patients terribly temperature-sensitive. An example is multiple sclerosis. Individuals with MS can suffer serious increases in their symptoms if their body temperature rises even a little bit. They may lose vision, balance, the ability to walk, or the ability to think clearly. Could they be protected from the effects of heat by cooling their natural heat portals? Evidence suggests that some cancer treatments could be augmented by the induction of hyperthermia and that the consequences of stroke or heart attack could be lessened by timely induction of hypothermia.

Review

- 9.4 The four avenues of heat exchange between an animal and its environment are radiation, convection, conduction, and evaporation.
- 9.5 Endotherms produce and conserve metabolic heat to offset heat loss in cold environments.
- 9.5 The basal metabolic rate (BMR) of an endotherm is the lowest metabolic rate necessary for biochemical and physiological processes of a resting animal.

Original Paper: Karpovich, S. A., Ø. Tøien, C. L. Buck and B. M. Barnes. 2009. Energetics of arousal episodes in hibernating arctic ground squirrels. *Journal of Comparative Physiology* 179: 691-700.

During winter, hibernating small mammals alternate between 1- to 3-week torpor bouts at low body temperature and 1- to 2-day returns to normal mammalian body temperature. These intermittent arousals from torpor include three phases: warming, maintenance of normal body temperature, and recooling. This pattern is repeated in hibernating small mammals regardless of the environmental temperature. Does the environmental temperature make a difference in

metabolic rate as the animals transition through these three phases?

Researchers set up hibernation chambers for arctic ground squirrels (*Spermophilus kennicottii*). In nature, their winter burrows can reach -10°C. The laboratory chambers were held at either +2°C or -12°C. All squirrels entered repeated bouts of torpor. During periods of arousal, body temperatures (T_b) and metabolic rates of individual squirrels were measured. Recordings of two individual squirrels are shown in the figure at right. They are representative of the squirrels assigned to the two groups.

The table reports the mean values during the rewarming phase for metabolic rate and body temperature plus or minus ($\pm$) the standard error for the two groups of squirrels at the different ambient temperatures. An asterisk (*) indicates that the mean values were significantly different from each other.

Environmental temperature (°C)	Starting body temperature (°C)	Time to reach $T_b = 30^{\circ}\text{C}$ (h)	Peak metabolic rate (mL $\text{O}_2/\text{g/h}$)	Total O_2 consumption from initiation until $T_b = 30^{\circ}\text{C}$ (mL O_2/g)	Time to peak metabolic rate (h)
+2	2.37 ± 0.38	5.65 ± 0.51	2.65 ± 0.22	5.42 ± 0.28	4.25 ± 0.30
-12	$-1.44 \pm 0.40^*$	$8.20 \pm 0.89^*$	$3.40 \pm 0.18^*$	$7.71 \pm 0.34^*$	$7.08 \pm 0.65^*$

Questions

- Did environmental temperature significantly affect the time to reach a T_b of 30°C? Did the initial body temperature affect the rate of rewarming? Explain your answer.
- Using the explanation in the chapter for an energy budget, explain why it took significantly longer for one group of squirrels to reach normal body temperatures and why their total O_2 consumption was significantly

different from that of the squirrels in the other group.

3. During the warming period, the subjects engaged in limited gross or large body movement. Describe the mechanisms and processes these squirrels used to raise their body temperatures.

Animal Hormones

Sex hormones are responsible for the dramatic differences between these male and female red deer (*Cervus elaphus*).

key concepts

- [10.1 Hormones Circulate Around the Body and Affect Target Cells](#)
- [10.2 The Endocrine System and Nervous System Work Together](#)
- [10.3 Hormones Play Important Roles in Development](#)
- [10.4 Hormones Regulate Metabolism and the Internal Environment](#)

The Exercise Hormone

Some active people eat a lot and never put on weight. Do they stay thin simply because exercising burns excess calories that would be stored as fat? There are two kinds of fat. “White” fat stores lipids, and “brown” fat metabolizes lipids to produce heat without producing ATP. Brown fat is present in cold-acclimated rodents, hibernators, and newborn humans, but it was not thought to be present in adult humans. Recently, imaging techniques revealed brown fat activity in cold-exposed adults. What is interesting is that the amount of brown fat is inversely proportional to total body mass—lean people have more brown fat and obese people have less. Perhaps the excess calories burned by brown fat contribute to low body mass.

A recently discovered signaling molecule may explain the difference in individual propensities to put on weight. Because this molecule, which was named irisin, circulates in the blood, it was designated a hormone. Irisin was discovered in a strain of mice bred for increased exercise endurance capacity, and it was shown that the irisin molecule is produced in and released from active muscles.

Training causes numerous structural and metabolic changes in muscle. Training also improves many other aspects of health. How are these changes mediated? Analysis of fat tissue from the super athletic mice showed a remarkable finding: their white fat had properties of brown fat. Moreover, this “browning” of white fat was triggered by irisin. That is, active muscles in mice signal white fat to change its properties to become metabolically active, burn more calories, and produce more heat. So in addition to improving the condition of muscles, exercise also causes muscles to “talk” to white fat, telling it to “shape up.”

Lots of questions followed the discovery of irisin in mice. Is it produced in humans during exercise? Does it have effects on tissues other than fat? Might other benefits of exercise be attributed to it? More research is under way.

This chapter covers the remarkable roles that hormones play in regulating physiological systems. A hormone is a chemical message that circulates in the blood and activates distant target cells. The power of hormones to initiate physiological change is reflected in the name irisin. Iris was the messenger of the Greek gods, traveling the world with the speed of the wind.

In what ways could irisin mediate the health benefits of exercise?

40.1 Hormones Circulate Around the Body and Affect Target Cells
